Saline County (Ark.) Medical Society.—The following officers were elected at a recent meeting of this organization held in Benton: *President,* Dr. J. W. Melton; *Vice-President,* Dr. Charles Prickett; *Secretary and Treasurer,* Dr. Charles Steed.

Massachusetts General Hospital Alumni Association.—More than 160 members of this association were present at the second annual banquet held in Boston on March 16. The officers elected for the ensuing year are: *President,* Dr. Ellery Stedman of Boston; *Vice-Presidents,* Dr. Dudley P. Allen of Cleveland, Dr. John Brannan of New York, and Dr. W. N. Swift of New Bedford; *Secretary,* Dr. F. A. Washburn, Jr., reelected.

Professor von Bergmann of Berlin, the well-known German surgeon, died of appendicitis at Wiesbaden on Monday of this week. He was operated upon the day before his death. Last summer he presided over a series of three meetings of the Berlin Medical Society devoted to a discussion of appendicitis, and voiced an emphatic opinion in favor of early operation, as a necessary preliminary to which was early diagnosis. He was born in Livonia, December 16, 1836, and studied medicine at the Universities of Dorpat, Berlin, and Vienna. During the Austro-Prussian war of 1866 Prof. von Bergmann was at the head of the military hospital at Koeniginhoff, Bohemia, and during the Franco-Prussian war he directed the military hospitals at Mannheim and at Carlsruhe. He was appointed professor of surgery at Dorpat in 1875 and remained there until the outbreak of the Turko-Russian war, when he was attached to the Russian army of the Danube as consulting surgeon. In 1878 he became chief surgeon of the hospital at Würzburg and was called in 1882 to succeed Prof. von Langenbeck in the chair of surgery at the University of Berlin and in the direction of the surgical clinic of that city. He operated upon the Emperor, Frederick III., and maintained, in opposition to Morell Mackenzie and Virchow, that the growth was cancerous.

In Memory of Dr. Fowler.—On Easter Sunday the Society of Ex-Internes of the Seney Hospital will unveil a bronze tablet in memory of the late Dr. George R. Fowler. The tablet bears the following inscription, and will be placed in the main hall of the hospital: "In memory of Dr. George Ryerson Fowler, surgeon in the Methodist Episcopal Hospital, 1887-1906. This tablet is erected by the Society of Ex-Internes in grateful recognition of him as teacher, counsellor, friend."

Obituary Notes.—Dr. John H. Brinton died at Philadelphia on March 18, at the age of seventy-five years. He was graduated from Jefferson Medical College in the class of 1852, and subsequently spent a year in foreign study. In 1853 he gave a course of demonstrations in operative surgery at the anatomical rooms in College avenue. In 1859 he was elected surgeon to St. Joseph's Hospital, and he was consulting surgeon to this hospital at the time of his death. In 1861 he was commissioned by President Lincoln brigade-surgeon of Volunteers, and he was assigned to the office of the Medical Director of the District of Cairo, where he assumed the duties of Acting Medical Director on the staff of General Grant. He subsequently acted as Medical Director of the Army of the Tennessee, with the rank of Major. In 1862 Dr. Brinton was assigned by Surgeon-General Hammond to the office of the Surgeon-General, where he was ordered to prepare a "Surgical History of the Rebellion." A short time later he was assigned to the founding of the Army Medical Museum. At a later period he was assigned to duty in the Department of Missouri, and he served as Medical Director in the field during the Missouri campaign. Still later he served as Superintendent and Director of General Hospitals at Nashville, and afterward as Acting Medical Director of the Army of the Cumberland. On his return to Philadelphia at the close of the war Dr. Brinton was appointed lecturer on operative surgery in the summer course at Jefferson Medical College, and a few years later was made one of the surgeons to the Philadelphia Hospital. In 1877 he was elected surgeon to Jefferson Hospital, and in 1882 Professor

of Surgery and of Clinical Surgery in Jefferson Medical College. This last position he resigned a year ago when he was elected Emeritus Professor.

Major William J. Wakeman, Surgeon U.S.A., died on March 20 at Fort Monroe, Va. He was born in Connecticut in 1845. After receiving his degrees in arts and medicine from Yale University he was made assistant surgeon in the army in 1882. He served through the Spanish war as surgeon of Volunteers, and in 1900 received the rank of Major.

Dr. Rodney C. F. Combes of Brooklyn died on March 18 of typhoid fever which he had contracted while on a trip through Mexico. He was born in East Rockaway, L. I., fifty-one years ago.

Dr. William B. Thomas of Ionia, Mich., died on March 5, at the age of seventy-six years. He was born in Monroe County, N. Y., and after being graduated from Genesee College, the University of Buffalo, and the University of Michigan, he began practice in Ionia in 1859. He served in the Civil War, and in 1866 was appointed United States Marshal. In 1871 he was Superintendent of Schools of Ionia county, and in the same year was admitted to the Bar.

Dr. James Utley of Newton, Mass., died on March 15 at the age of sixty-eight years. He was born in Chatham, N. Y., and received his medical education in the Bowdoin Medical College and the Hahnemann Medical College of Philadelphia. He settled in Taunton early in the sixties, but some years later removed to Newton, where he had since resided.

Dr. J. J. Hopkins of Upper Tract, W. Va., died suddenly on March 14, at the age of sixty-four years. He was graduated from the New York University Medical College in 1874.

Dr. W. J. Sneed of Nashville, Tenn., died on March 17, at the age of seventy-two years. He was born in Brentwood, Tenn., and was graduated in medicine from the Vanderbilt Medical College, in which institution he was afterward professor of anatomy. He served as surgeon in the Confederate Army and had practised in Nashville for over forty years.

Dr. Albert M. Warner of Waukesha, Wis., died on March 15, at the age of ninety-one years. He was born in Andover, Vt., and was graduated from the Vermont Medical College at Woodstock in 1842. After practising a short time in New York, he removing to Waukesha, where he had resided ever since.

Dr. J. L. Edgar of Clearwater, Fla., died suddenly of apoplexy on March 13. He was a native of Missouri, and had practised in Florida for over twenty-five years.

Dr. David H. Shenk died at Lancaster, Pa., on March 11, at the age of fifty-five years. He was graduated from Long Island College Hospital in the class of 1874.

Dr. Leander P. Jones of Greenwich, Conn., died on March 18 at Bellaire, Fla. Dr. Jones was born in 1845 in southern Vermont. He was graduated in 1874 from the New York College of Homeopathy. After practising for a time in Hartford, he went to Greenwich in 1876. In 1894 he was elected State Senator, and at the close of his term was asked to take the nomination for Governor, but declined. He was for many years fleet surgeon of the Indian Harbor Yacht Club, and had just been reappointed to that office. He had held numerous public offices, and at the time of his death he was medical examiner for Greenwich.

Dr. Robert Stewart MacGregor of this city died of pneumonia on March 23, at the age of thirty-eight years. Dr. MacGregor was born in St. Andrews, Province of Quebec. At an early age he moved to this State. In 1894 he was graduated with honors from Brown University, and three years later he finished the medical course at New York University. Since that time he has practised medicine in this city with the exception of one year which he spent in a hospital at Yonkers.

Obituary.

GEORGE G. WHEELOCK, M.D.

NEW YORK.

Dr. George G. Wheelock of this city died on March 22, at the age of sixty-eight years. He was born in Boston in 1838, and took his bachelor's degree at Harvard College in 1860, and his master's degree in 1864. In that year he also took the degree of Doctor of Medicine at the College of Physicians and Surgeons of this city. He entered the Government medical military service, and was for a year in charge of the General Hospital at Savannah, Ga. He later served as house surgeon in the New York Hospital, and, after some time spent in study abroad, began practice in New York. He soon received the position of Assistant Demonstrator of Anatomy and Lecturer on Physical Diagnosis in the College of Physicians and Surgeons, becoming later a Trustee of the college, and Registrar of its Board of Trustees, and serving for many years as Treasurer of the Association of the Alumni. He was also appointed attending physician to St. Luke's Hospital, and to the Nursery and Child's Hospital. In 1891 Dr. Wheelock was elected a Trustee of Columbia, and became a manager of the Vanderbilt Clinic and of the Sloane Maternity Hospital, all of which offices he held at his death, being President of the last-named institution. Dr. Wheelock retired from the practice of medicine in 1891, and since then had given his time to the service of the various public works in which he was interested.

OUR LONDON LETTER.

(From Our Special Correspondent.)

HUMAN AND BOVINE TUBERCULOSIS—TROPICAL SANITATION—CEREBROSPINAL FEVER—A CLERIC DENOUNCES ROBBING THE DOCTOR—OBITUARY.

London, March 8, 1907.

At the Medico-Chirurgical on the 26th ult. Dr. Nathan Raw read a paper on Human and Bovine Tuberculosis, having special reference to treatment by corresponding varieties of tuberculin. He held that infection of the human body may be by either bacillus, the two being varieties of the same species, but giving rise, according to the method of infection, to quite different and distinct lesions. The cultural differences were sufficient, when typical, to differentiate them, but the microscopic appearances were not. Basing his conclusions on 4,000 cases of phthisis, including 700 post-mortem examinations as well as on animal inoculation, Dr. Raw divided the lesions in the human species into two groups: (1) Lesions caused by the T. B., *typus humanus;* phthisis pulmonalis, secondary intestinal ulceration, tuberculous laryngitis; (2) caused by the *typus bovinus* (conveyed by meat, milk, etc., or by direct infection), acute miliary tuberculosis, primary intestinal and mesenteric disease (tabes, peritonitis, pelvic tubercle), tuberculous lymphatic glands, tuberculous joints and bones, lupus, tuberculous meningitis and tuberculous ulcerations of the cornea. Human and bovine tuberculosis were antagonistic and one could confer immunity from the other. Dr. Raw had had a new tuberculin prepared based on these observations.

Dr. David Lawson remarked on the rarity of surgical

tuberculosis in pulmonary phthisis. Out of 600 or 700 consecutive cases none had lupus, only three bone disease and only five gland affection. The frequency of miliary tuberculosis as a termination of phthisis required explanation. There were some good results in phthisis from T. R. tuberculin as checked by the opsonic index, though not so striking as in surgical tuberculosis.

Mr. J. P. Lord asked whether the two groups could be distinguished in milk.

Dr. C. Calvert said the Royal Commission had reported both bacilli found in cervical glands. He thought the two were varieties—not types.

Dr. Tooth inquired as to the precautions which had been adopted in regard to injections.

Dr. Sandwith said all forms of tuberculosis were common in Egypt except meningitis. He found injections gave bad results in surgical cases. He had not seen lupus in a phthisical case. The women in Egypt suckled their children even for two years and all other milk was generally boiled and tubercle among cattle was rare. Nevertheless tuberculosis was frequent.

Professor Ronald Ross gave a lecture last Friday at the Sanitary Institute on "Points of Interest Connected with Tropical Sanitation." The Duke of Northumberland, president, paid a well-merited tribute to the indefatigable labors of Dr. Ross in the field of tropical medicine, and at the close proposed a vote of thanks to the professor for his instructive lecture. Dr. Ross showed a number of lantern slides to illustrate the history and progress of sleeping sickness, yellow fever and malaria, and said we now know as much about the anatomy of the tsetse fly, which carries the sleeping sickness parasite, as we do of the anatomy of the human body. It was not possible to get rid of the larvæ of the tsetse fly, so the only way to prevent the spread of the disease is to cure it in the patients. It is depopulating whole districts in Africa and many almost despair of combating it. Quarantining trade routes is one of the latest proposals. The lecturer then gave an account of the discovery that yellow fever is caused by the bite of the tiger mosquito, but the parasite it introduces has not yet been discovered. Dealing with malaria, he insisted on the importance of draining the soil, and referred to the effort about to be made to clear the valleys of Greece of this devastating disease.

I have received from the County Council a copy of an order making cerebrospinal fever notifiable in the administrative county of London for six months from Tuesday next. The council has also sent with the notice extracts from a memorandum dated July, 1905, by Mr. Power, M.O.H. of the Local Government Board. This board has issued a report by Dr. M. H. Gordon, dealing with the micrococcus especially in reference to its identification in the upper respiratory tract. He finds the agglutination test of little value for distinguishing the meningococcus from normal cocci of the mouth and throat.

The Surrey Medical Officers of Health held a meeting last Friday to discuss preventive measures. Cases have been reported in various districts, but some are probably not cerebrospinal. One or two have occurred in the suburbs of London; yesterday an inquest on a child resulted in a verdict that death was due to the disease. In Ireland and Scotland the epidemic has continued.

The clergy are generally so little appreciative of the profession that a recent word by Father Vaughn deserves notice. He has been giving a series of sermons on the "Sins of Society," which he expressly directs to the "smart set." Last Sunday he addressed them on Truth, telling them that as Pilate had no place for it in practical politics, so it was in their "grab for riches, push for place, and rush for honors." To-day, he said, men and women did not pause to reckon with truth but indulged in forms of speech which "were lies as black as the 'father of lies' himself." For instance, society women made themselves out poor when it suited them, as in one case under his notice when a famous oculist had been robbed of his fee for an operation by a pretense of poverty. Now that woman, said the preacher, not only defrauded the oculist but she also defrauded some poor sister of a free operation, because there was a limit to the number of cases which, even one of the most generous class of men, physicians and surgeons, could undertake without fee.

Dr. Allan Macfadyen died on Friday last at the early age of 46. Educated at Edinburgh University, he afterwards studied in London, Berne, and Munich. From 1889 to 1892 he held the Sanitary Research Scholarship founded by the Grocer's Company. He was connected later with the Jenner Institute (now the Lister), and was Professor of Physiology at the Royal institution. His bacteriological work is well known. To the Local Government Board Reports, 1889, he contributed an important paper on the "Chemical Action of Bacteria on Albumins and Peptones." A number of papers from his pen detail his researches as to the possibility of immunizing animals against typhoid, cholera, plague, and other diseases, were regarded as of high value, and it seems sad that he should not have lived to complete his work. It would require a bacteriologist to do justice to his investigations.

Lt.-Col. G. M. McKee of the Indian Medical Service died on the 27th ult., aged 52. He entered as assistant surgeon in 1880 to the 83rd light infantry, served in the Burmese Expedition, 1885-7, and obtained the medal and clasp. He became Lt.-Col. in October, 1900.

Lt.-Col. E. Fitz-Stubbs, late Army Medical Service, died on the 28th ult., at the age of 60. He entered the army in 1871 and retired in 1896. He had the Ashunti medal (1873-4) and the Egyptian medal and bronze star (1882).

A HEALTHFUL SPORT.

To the Editor of the Medical Record:

Sir:—Rifle shooting as a means of relaxation does not receive the attention it should. It trains the eye to see accurately, the mind to judge correctly, and exercises the powers of coordination, while the strict attention it requires takes the mind clear of business cares and all the other worries and irritations of modern life. It is the sport par excellence for the neurasthenic, for he is obliged to forget himself, and introspection for the time becomes impossible when every faculty is centered on a target maybe five hundred yards away.

While it can be indulged in during the winter or in bad weather in some indoor gallery, its perfection as a sport and change for the busy professional man or merchant is found out on the range under the blue sky, where fresh air, good company, and attention to the business in hand cause all cares to "fold their tents like the Arabs and silently steal away." Add to these advantages the fact that it is in itself an act of patriotism, qualifying a man to fulfill one of the highest duties of citizenship, the defense of his country in time of need.

The time was when the country was new that we were a nation of riflemen, but that is no longer the case, and special efforts must now be made to have a sufficient supply of marksmen. Therefore, every man should lend his encouragement to this sport which is clean, healthful, and patriotic. You or I may feel that we never would be called upon to use that skill directly; but by example and support we may excite enthusiasm in others and use what skill we may obtain in helping to train others.

In a short time there will be scarcely a town of any considerable size which will not have a branch of the National Rifle Association. The United States Government is assisting these clubs in every way, and if the physicians of the country would take an active part they would derive great physical benefit themselves, do their duty by their country, and help make popular a sport which all could take part in, as it does not require severe physical exertion, nor does it, like other field sports, tempt its devotees to overtax their strength.

Long range shooting especially cultivates the powers of observation, mathematical reasoning, and logical deduction to a degree unknown to any other sport, while, at the same time, it is free from envy, spite, and the littleness of many other forms of personal competition. Many doctors realize this, and a very large proportion of the expert shots of this country are doctors—notably Dr. W. G. Hudson, to whose work in perfecting the modern high power bullet the United States Government owes a large debt of gratitude.

William C. Wood, M.D.

Gloversville, N. Y.

SULPHATE OF COPPER IN TYPHOID FEVER.

To the Editor of the Medical Record:

Sir:—Hare says in his Practice of Medicine: "Very recently it has been shown in the United States Government Laboratories at Washington, and in the City Laboratory at Philadelphia, that so small an amount of sulphate of copper as 1:1,000,000 or even 1:4,000,000, will destroy the typhoid bacillus in a few hours." When so high an authority makes such a statement it may well give us pause. If this attenuated dilution (almost Hahnemannian) will destroy the bacillus typhosus in tanks and reservoirs, why not within the human body? The proportion of 1:1,000,000 is approximately one grain to sixteen gallons of water. The average human body contains perhaps sixteen gallons water. To immunize the average person from typhoid fever it is therefore necessary to incorporate with it one grain of sulphate of copper. The salts of copper being diffusible substances quickly enter the blood and are eliminated by the liver, intestinal canal, salivary glands,

and kidneys. In the blood, as is the case with other metallic poisons, copper probably exists in the form of an albuminate in close relation with the red blood globules. It would seem that copper in any form is fatal to the typhoid germs. How it acts is not known. It has also been stated that if water containing typhoid bacilli is placed in burnished copper vessels for a few hours most of the typhoid germs are destroyed.

If our premise is correct the conclusion follows: Given one grain of sulphate of copper, say every four hours for possibly three days, all the typhoid germs will have been destroyed and the disease aborted. If given after necrotic changes have taken place in the intestinal glands, convalescence would be delayed until sufficient time for repair, perhaps one week, or at most ten days or a fortnight.

When one has a case of typhoid fever, let him follow these suggestions. It will not interfere with other treatment, which it may be well to add should not be neglected —at least not for the present. J. L. GILBERT, M.D.

KENDALLVILLE, IND.

Progress of Medical Science.

New York Medical Journal, March 16, 1907.

General Infection by the Colon Bacillus with Rapidly Fatal Septicemia and Hemoglobinemia.—The patient of A. D. Blackader and B. D. Gillies was a young woman of twenty-seven years, apparently in good condition, who was stricken down and died within forty-eight hours, developing an extreme hemolysis before death. There had evidently been an abortion between the second and third months of pregnancy and this had been followed by the usual toxic symptoms, which in turn were succeeded by a colon bacillus infection of the uterus, as shown by smears and cultures. Later severe septicemia developed and finally a rapid destruction of the blood cells. A full history is given with autopsy findings. The authors consider that the rapid hemolysis is the most interesting feature in the case, and they refer to the literature of the special lysins, the products of various bacteria, such as the *B. pyocyaneus, B. typhosus, B. coli communis, B. Staphylococcus albus*, and *aureus* and *Streptococcus pyogenes*. The development of these lysins is in the main extrabacillary. It begins on the second or third day and increases rapidly to a maximum on the sixth or seventh, after which it slowly decreases. The authors quote freely from Abbott with reference to this class of substances. So far as they know, no previous case on record has brought to light any such severe grade of hemoglobinemia.

Trachoma, Clinically and Socially Considered.—A general description of the disease is given by H. F. Hansel, who also alludes to the national regulations bearing on the subject. The article traverses familiar ground and nothing new is brought out. The author believes that immigrants who have reached the cicatricial stage of the malady, with eyes otherwise in good condition, may be allowed to land.

Rhinoscleroma Treated with the X-Ray.—After a brief allusion to the nature of the disease and its geographical distribution, M. J. Ballin relates one personal case occurring in a Russian woman of fifty-three years. Photographs are shown in the paper by which the progress of the case can be traced. The noteworthy features of the case are: first, its long duration, viz. sixteen years; second, the complete freedom of the larynx; third, the extremely large size of the nasal organ, and fourth, the surprisingly good effect of the *x*-rays in treatment. At the time of the report the case was not absolutely cured, but a vast improvement had been made, although there was some obstruction inside the nares. Removal of pieces of affected tissue to allow of a greater air space are generally followed by increased activity of the pathological process. It is hoped by the author that the use of very small tubes for the *x*-ray within the nose will result in a full restoration of their patency, or at least lead to satisfactory cicatrization. It is thought that the reduction of size of the nose has been due not to a breaking down of the tissue, but to a gradual absorption brought about by some chemical change.

The Significance of Bladder Symptoms in Relation to Some Spinal Cord Lesions.—Five cases are detailed by J. B. Squier, who speaks of the necessity for closer discrimination between urinary symptoms arising from degenerative changes in the motor or sensory centers in the cord and those due wholly to organic conditions in the bladder and its adnexa. Concerning the bladder symptoms in tabes the author says that it is of the utmost importance to seek out and treat, if they be present, any lesions of the urethra which may add peripheral irritation to the already degenerated cord centers. The treatment of vesical conditions due to spinal cord lesions is more or less identical to that of the organic local disease by which they are similarly produced. The spasm of the irritable stricture can be relieved by the passage of a sound, and in like manner the vesical spasm of tabes may be relieved by the same procedure. The treatment of these cases frequently gives results far beyond that which one would be led to expect, in consideration of their causative factor. The utmost of persistence and perseverance is required, and nowhere in the realm of medicine is the carrying out of the details of treatment more necessary. A tabetic bladder should never be allowed to become overdistended. If it becomes necessary to place the catheter in the patient's hands the most rigorous instruction in the technique of aseptic catheterization is imperative. Trophic disturbances are common to the disease, and on this account the patients are especially prone to infection, and a tabetic bladder once infected is no easy matter to restore to a state of asepsis. Further, the smallest source of irritation should not be overlooked. Sometimes the mere division of an abnormally small meatus will do much towards relief of a vesical spasm. Mitchell, Frenkel, and others have accomplished considerable for the ataxia of tabetic patients by motor reeducation. In like manner a certain amount can be gained in relieving the weakened viscus by educating the abdominal muscles to aid the vesical detrusor. Of the drugs, belladonna administered internally is the most efficient to relax vesical spasm. For toning up the bladder and preventing inflammation, solutions of silver nitrate act better than the newer silver salts.

Journal of the American Medical Association, March 23, 1907.

Simple Ulcer of the Bladder.—G. Walker gives a report of two personal observations of this comparatively infrequent condition, which he defines as a single non-inflammatory ulcer of the mucous membrane of the bladder, occasionally penetrating the entire wall, and due probably to local disturbance in, or complete blocking of the terminal or by an interference with the trophic nerves, and never produced by infection of the bladder, though in its second and third stages it becomes infected with the ordinary pyogenic organisms. Two types are recognized: the simple chronic form leading to cystitis, and the acute perforating ulcer. The early symptoms of the chronic type are those of irritation; increased frequency of micturition, scalding, pain, etc., and later cystitis with aggravation of all the symptoms, finally, bladder paresis and the patient, unless relieved by operation, succumbs to exhaustion or ascending infection. In case of the acute perforating ulcer there are no symptoms whatever until perforation occurs. In the earlier stages the cystoscope affords the only means of diagnosis, and shows a simple ulcer with cleancut and slightly indurated edges surrounded by normal mucosa. It is distinguished from tuberculous ulcer by its clean, not undermined edges, the appearance of its base, the absence of surrounding tubercle, and of tuberculosis elsewhere. Only in this early stage can it be distinguished from the ulceration of the various forms of cystitis, and Walker believes that many cases of diagnosed healed tuberculosis cystitis were primarily this disease. The prognosis of simple ulcer in the early stage is good if proper treatment is given. In the second stage, when lime salts have been deposited and the ulcerations are exaggerated, curetting and drainage will generally effect a cure. In the third stage, when there is great interstitial change, the prognosis is grave, and the acute perforating ulcer is usually fatal, practically always so when the peritoneum is involved. One very early recognized case is reported by Harrison, in which the patient was cured by operation. Silver nitrate irrigations, from 1 to 10,000 up to 1 to 5,000, every second day will usually cure in the first stage. In the second stage, curetting and cauterization with prolonged suprapubic drainage are generally necessary. In the third stage, drainage, irrigation, and gradual bladder distention are all that can be done.

The Nasal Accessory Sinus and Eye Diseases.—F. E. Brawley calls attention to what he considers a practically unrecognized condition, rarely attributed to the nose and almost always to the eyes, and the fact that glasses will sometimes give temporary relief tends to confirm the error. The origin of the trouble generally dates back to an attack of grip or a hard cold, and the

headache when it first appears is often unilateral, though later becoming general. It occurs both by night and day, often beginning and ending at regular hours. During the attacks the use of the eyes is almost impossible, as it intensifies the symptoms; insufficiency, both of accommodation and convergence, is usual, and distant vision may be reduced. There is often unilateral lacrymation with local pain and swelling about the eyes. Stooping over especially aggravates it, and it is affected by jarring, circulatory disturbances of any kind, excesses in eating, etc. As a rule, there is no history of nasal disease. A close examination will reveal a swollen, boggy turbinal or one so closely applied to the lateral nasal wall as to press on the hiatus semilunaris and to interfere with the interchange of air and exit of normal secretions from the frontal and anterior ethmoidal cells. If the use of suprarenalin and cocaine to the middle turbinal and infundibulum relieves the attack, a resection of the hypertrophied anterior end of the middle turbinal is indicated to restore normal conditions of air interchange and exit of secretions. The point specially emphasized in his paper is the absence of all definite nasal symptoms and the apparently normal nose. There may be more serious conditions, however, such as acute suppuration of the sinus producing these symptoms. It is in the milder non-suppurative case that the real cause of the condition is likely to be overlooked.

Eyestrain as the Cause of Chronic Headache.—Basing himself on his records of nearly 1,300 eye examinations, S. W. S. Toms claims that ninety per cent. of all those suffering from reflex or neuralgic headache have ocular defects. Over six hundred of the patients examined were altogether unaware of their defect. Fully half the cases were of only slight refractive errors or muscular imbalance, and it is in these cases in which ciliary spasm is the direct factor in causing headache in persons whose occupation calls for near vision, that accommodative asthenopia results. While there were occasional complications, only five per cent. of the patients had discoverable organic lesions that possibly intensified or were partly to blame for the head pain. Of those who were relieved of their headaches seventy-five per cent. had no other treatment than properly adjusted glasses or appropriate treatment for their muscular anomalies. The types most frequently met are the occipito-cervical, fronto-temporal and the hemicranias. There is no apparent relation between the severity of the headache and the degree of the ocular defect, and nothing especially characteristic except, perhaps, the patient's non-suspicion of the cause. Sickness or health impairment may be the first inciting factor in some patient with considerable ocular defects which gave no trouble before. In this connection, the author mentions as an ocular condition that does not receive the attention it deserves in young subjects, subnormal accommodation, or premature presbyopia, which may be the cause of alarming symptoms of headache and insomnia. Such patients often have a very acute vision for distance, with a slight muscular trouble of exophoria or esophoria, which is a misleading condition. They refuse all distance lenses or prisms, but find immediate relief when a presbyopia correction is made.

Examination of Students' Eyes.—W. C. Posey and R. T. McKenzie describe the methods and results of the examination of the eyes of 883 students of the University of Pennsylvania during the college year of 1905-06. So far as known, the University of Pennsylvania is the only degree-conferring institution in which such examinations are systematically made. Of the total number examined, 640 were students in the college department, 108 in the medical, 81 in the dental, 51 in the law, and 3 in the veterinary department. Of this total 14.70 were found myopic, the remainder being either hypermetropic or emmetropic. As regards the evidence of the influence of age and study, it is stated that among over 600 students in the two lower classes, 87.25 per cent. were hypermetropic and 12.75 per cent. myopic; while of 261 in the upper classes, 80.25 per cent. were hypermetropic and 19.75 per cent. were myopic. Five per cent. more of myopia was found in the professional departments in scholars of similar age than in the college department, which is accounted for by the larger number in the former from the rural districts, where the care of the eye is more apt to be neglected. The average age of all students was 21.4 years, and the statistics showed an increase of about 2.5 per cent. of myopia for each of the four years of college life. Of the students examined, 609 had full visual acuity of both eyes, 94 had it in but one eye, while 180 had subnormal vision in both eyes. These latter were decidedly at a disadvantage in certain forms of classroom work, irrespective of effects of uncorrected strain, while those with only one eye with normal vision were handicapped in the proper use of scientific instruments. Three hundred and three students wore glasses, 217 were hypermetropic, and 86 myopic. Eighty-seven complained of headache, 47 of these wore glasses. Of those with headache only, 7.59 per cent. had subnormal vision; the remainder were normal and therefore did not credit it to their eyes. Fifty-eight of the total number had scoliosis, or 6.68 per cent., 48 were hypermetropes, and 10 myopes. In 13.79 per cent. of the spinal curvature cases the vision of one eye was perceptibly lower than that of the other, supporting the inference of some ophthalmologists that ocular errors may cause this abnormality. The authors think that these figures, which are only a few out of the many compiled from the examinations, sufficiently indicate the importance of careful ocular tests as a part of the physical examination of every student and the importance of correcting existing errors.

Insanity in Women.—W. O. Henry reviews the literature of the subject, quoting the opinions of various authorities and criticising some of them who have minimized the value of gynecologic operations for the cure of insanity in women. He gives very brief reports of 28 cases, in which he operated on such patients; of this number he claims that 16 recovered from their mental disorders, 3 of them having remained well nine, ten, and eleven years, respectively. He thinks that there is a vast amount of undiscovered pelvic disease in insane women, the relief of which by operative methods would be possible. He insists on the necessity of radical work in these cases so as to leave no possible source of irritation that might perpetuate the insanity.

The Lancet, March 9, 1907.

Dislocation of the Semilunar Bone Complicating Fracture of the Styloid Process of the Radius.—P. R. Wrigley reports a case of this injury, his patient being a painter, thirty-five years old, who fell thirty feet from a ladder, dropping on his feet and then on his outstretched hand. The injury was at first supposed to be a Colles' fracture. The author who saw the case some days later found a transverse lacerated wound one inch long in front of the inner side of the wrist swollen, but permitting the recognition of the radial fracture. Later a rounded projection of bone was noted on the front of the wrist to the inner side of the palmaris longus tendon. An *x*-ray picture revealed a forward and upward dislocation of the semilunar bone, which lay just in front of the articulation between the radius and ulnar, the condition being complicated by a vertical fracture of the radius severing the styloid process from the rest of the radius. As the dislocated bone seemed too firmly fixed for reduction and the wound was suppurating freely, rendering excision inadvisable, it was judged best to await events. The wound healed in about a fortnight when splints were discarded and massage and active movements were commenced. This treatment was carried out for about a month with a gradually increasing range of movement of the wrist and fingers, but the patient began to complain of a feeling of numbness and tingling in his ring and little fingers. This was followed by characteristic ulnar paralysis affecting these fingers and in a minor degree the adductors of the thumb. It was obvious that if permanent injury to the ulnar nerve was to be avoided the offending bone must be removed. Ten weeks after the accident the semilunar bone was removed through a vertical incision. It was firmly imbedded in fibrous tissue, the ulnar vessels and nerves being displaced outwards. Healing resulted by first intention and massage was begun. In five weeks the ulnar paralysis had almost disappeared, there being only slight flexion at the interphalangeal joints of the little finger; the movements of the wrist were good and daily increasing in strength and range, so that the patient has now begun to do light work.

Operative Treatment of Traumatic Psychosis.—A case report is made by B. Hollander, whose patient was a physician of thirty-nine years, who had been kicked on the right side of the chin by a horse and who a year later had a bicycle accident, falling on the right side of his head. There were no visible signs of injury, but the accident was followed by hemicrania of great severity, preventing any intellectual work, and by definite character changes. He became emotional, anxious, very depressed, accused himself of unpardonable sins, developed suicidal ideas, grew suspicious, easily offended, irritable and profane, erotic, and subject to uncontrollable fits of sexual excess. He suffered also from obstinate constipation, persistent insomnia,

and had sensory disturbances in the left arm. He sought relief in changes of scene by traveling, but to no effect, and his strange conduct frequently led him into difficulties. In the spring of 1905 (six years after the bicycle accident) he had symptoms of word blindness and a transient attack of paralysis of the right side of the face and left half of the body. The depression and headache increased and all medical treatment failed to cure him. Believing in the possibility of localization of mental functions, and hoping that if his symptoms were localizable operation would show pathological changes and give relief, he came to London. On examination on October 3, 1905, he appeared depressed, emotional, showed strong suicidal tendency, and complained of intense headache on the right side and a burning sensation just posterior to the right parietal eminence. It was ajudged that there was a lesion originally limited to the neighborhood of the supramarginal and angular convolutions, later spreading downwards over the posterior temporal region. When the head was shaved preparatory to operation a scar appeared two inches behind the right ear and two inches long, commencing behind the parietal eminence in the situation of the angular gyrus and extending vertically downwards, corresponding to the posterior part of the temporal convolutions. A semicircular flap was made, extending from the tip of the ear to the occipital protuberance. The scar tissues were found firmly adherent to the bone and had to be forcibly detached. Two trephine openings were made, one one inch in diameter, and the other 11-16ths of an inch just below and a little behind the other and joined together. The bone over the angular gyrus was found thickened and hardened, with scarcely any diploe and the dura mater was adherent to it. When the bone was demoved the dura mater bulged into the opening, but showed no signs of pulsation, although the pulse of the patient at the time was quite strong. On cross incision of the dura mater a stream of clear fluid escaped. The membrane was opaque and thickened, but the brain appeared normal and on examination the neighboring parts revealed no pathological changes. The dura mater was stitched together and the periosteum over it, the portion of bone not being replaced. A drainage tube was kept in the scalp wound for three weeks. The patient during this period had still occasional attacks of depression and irritability, headache, and trigeminal neuralgia, but with the closing of the wound all symptoms disappeared. Five weeks later the wound had quite healed. The trephine openings were felt through the scalp. The brain was felt pulsating beneath, but there was no protrusion. There was no tenderness of the surrounding nerves. The general condition was quite good. Three months later the patient reported himself as absolutely well. There had been no return of the insomnia, the headache, neuralgic pains, or the sensory disturbances in the left hand and arm. The obstinate constipation of the bowels that obtained throughout the case prior to the operation one and a half years ago had entirely disappeared. Mentally, he had lost completely his morbid suspicion and all suicidal thoughts. The attacks of mental depression, the erotic feelings and morbid sexual symptoms had likewise entirely disappeared. He had resumed interest in all the affairs of life. Surgically the head was perfect in appearance and there was no tenderness anywhere.

British Medical Journal, March 9, 1907.

Deafness or Myxedema.—J. W. King refers to a case of myxedema extending with intermissions throughout a period of four years, but always yielding to thyroid treatment. The patient, a man of fifty-six years, had unimpaired hearing previous to the initial attack four years ago, but on each subsequent attack he has invariably become so deaf as to hear only loud shouting.

Influenza and Epistaxis.—Case histories are given by J. Pugh Jones and J. E. Turnly, both cases presenting the usual febrile manifestations and intercurrent nose bleed. In one instance sodium salicylate had been given, and the author was unable to decide whether the epistaxis was due to the effects of this drug or was an accompaniment of an ordinary nasal sinus suppuration due to the influenza bacillus.

The Staining of Animal Parasites.—I. W. Hall gives the following directions. (1) Prepare a film of the blood, feces, or sediment of the secretion. Fix by heat, or, less preferably, by formalin vapor. (2) Treat the film with the following solution, one-half to two minutes: Watery methylene blue, one per cent., 100 c.cm.; glacial acetic acid, 5 c.cm. (Neisser's methylene blue solution may be equally well used if at hand. Methyl violet, Nile blue, etc., are not so good). (3) Wash in water. (4) Cover the film with saturated alcoholic eosin solution. Allow to stain for five or ten minutes, or (following Muir's excellent method described in the *Journal of Pathology*, 1906) heat over the flame, blowing out the alcohol each time it catches fire, until the film is almost dry. (5) Wash in water. (6) Fix in potash alum solution, one-half to two minutes. (7) Decolorize in ninety per cent. alcohol until a uniformly pink color obtains. (8) Wash in water; allow to dry; mount in Canada balsam. It is the treatment with acetic acid which affects the outer coverings of the ova, embryos, and parasites, and allows the stain to permeate the entire structure. The paper closes with the applications of the foregoing method to feces, sediments from secretions and cyst contents, filaria, adult parasites, and spores. Concerning adult parasites the author states that by this method the internal structures, particularly the reproductive organs and the ova, are well brought out. It is best to allow the parasites or the segments to remain in the acid solution for about one hour, and in the eosin solution over a night. After thorough drying with absorbent paper they are cleared in clove oil or xylol for twenty-four hours and then mounted in balsam.

The Treatment of Incipient and Borderland Cases of Insanity in General Practice.—The various forms of mental disease considered by the author are grouped under the headings of backward or deficient cases, the epileptic, the nervous, the moral imbecile, the incipient melancholic and maniacal, the borderland delusional, and the premature dement. Forms met with in adult life are incipient mania and melancholia, borderland delusional insanity, incipient general paresis of the insane, borderland alcoholic insanity, and associated mental unsoundness. In old age we have incipient senile mania and melancholia, borderland paralytic insanity, and incipient senile dementia. Under each of these headings are grouped the respective hygienic and medical measures the author has found most beneficial, such groupings following a summary of symptoms. The author claims that the chronic borderland insane cases are neglected at the present time, and that the voluntary boarder system which exists in England for registered hospitals and licensed houses must be extended to county and borough asylums receiving paying patients, to be used for patients of this class. Thus additional means will be obtained for skilled treatment in the early stages of mental disease. Since contact with certified insane persons undoubtedly has a demoralizing and injurious effect upon many of the incipient insane, individual treatment in single care, uncertified, with all the surroundings and comforts of home, is much to be commended. The tendency very rightly is at the present time to this decentralization and segregation, and he believes the best results will be obtained thereby.

Berliner klinische Wochenschrift, March 4, 1907.

The Connection of Lactic Acid with the Convulsions of Puerperal Eclampsia.—Donath considers the theories of Zweifel and his coworkers who ascribe to sarcolactic acid an important rôle in regard to the convulsive seizures in puerperal eclampsia. In order to investigate the power of this agent to evoke convulsions he first studied the cerebrospinal fluid of epileptics, usually obtained shortly after an attack, and in another set of experiments introduced considerable quantities of it into the circulation of animals. The fluid obtained by lumbar puncture from nine epileptics was examined but it was never possible to demonstrate the presence of any lactic acid. On injecting from one to one and one-half grams per kilo of neutral sodium lactate into dogs no symptoms of any importance were caused. The author therefore concludes that in eclampsia, as well as in epilepsy, the muscular action attending the convulsions induces the formation in the muscles of sarcolactic acid. This is then rapidly oxidized in the blood, and only a small portion of it is excreted unchanged in the urine. It is accordingly not to be regarded as having anything to do with the causation of the convulsions in eclampsia, and is simply a secondary manifestation of the muscular activity.

Münchener medizinische Wochenschrift, February 30, 1907.

The Effect of Narcosis on the Blood.—Mulzer studied the effect of ether and chloroform on the blood by subjecting animals to prolonged and very profound narcosis with these agents. He found that sections of the organs of these animals gave evidence of a noteworthy change in the character of the blood in the vessels. Alterations in the appearance of the red

blood cells led him to believe that these undergo serious damage, and structures were also discovered which he considered as being granules and strands of fibrin. These lesions were most pronounced in the vessels of the lung, and numerous control observations seemed to show that they were the direct result of the action of the anesthetic agents. Chloroform appeared to have a somewhat greater power to produce the changes than ether. The coagulability of the blood was slightly increased after narcosis and the hemoglobin was reduced. The number of erythrocytes was still diminished to a very considerable degree, and the abnormalities in the shape of the cells indicated the destructive action of the anesthetics.

Scopolamine-Morphine-Chloroform Narcosis.—Kreuter reports on one hundred cases of chloroform anesthesia preceded by two injections of scopolamine and morphine carried out in the Erlangen University Hospital. In eighty-six per cent. of the cases the results were satisfactory, while in the others little or no effect seemed to be produced by the preliminary injections. The general conclusion reached is very much in favor of the method, which is characterized as the ideal from the patient's standpoint, though an uncomfortable sequel is the trying sensation of thirst that commonly persists during the first twenty-four hours. This represents, however, one of the valuable features of the method, since it is due to the general inhibition of secretion that is caused by the alkaloids, and this, according to the author, is an important prophylactic against postoperative pneumonia. He considers that when the alkaloids are used in small amounts the method is free from danger, and it appears that a much smaller quantity of ether or chloroform is required. The disadvantages of the method lie in the uncertainty of action of the alkaloids and in the thirst that follows the operation. The method is contraindicated in operations about the face, mouth, or respiratory passages in which there is danger of aspiration, and expectoration is desired, but it may safely be resorted to even for long operations on weak patients. For details as to the technique employed in the Erlangen clinic reference must be made to the original.

Deutsche medizinische Wochenschrift, February 28, 1907.

Differential Stains for Distinguishing Tubercle from Perlsucht Bacilli.—Spengler says that in about sixty per cent. of the cases of phthisis the tubercle bacillus and the perlsucht bacillus are present in a condition of symbiosis. In order to assist in the recognition of such cases he suggests several staining methods. One of these is a capsule stain performed as follows: The smear is rendered alkaline with one per cent. solution of sodium or potassium hydrate and is dried without resorting to more than the least possible degree of heat in order to avoid injury to the extremely susceptible capsule of the perlsucht bacillus. Löffler's methylene blue is poured over the preparation, which is then washed with water. The preparation is next treated with carbol fuchsin solution heated gently until it steams, and is washed with water. Finally the preparation is stained for a few seconds with methylene blue, to which one or two drops of fifteen per cent. nitric acid have been added, is rinsed with water and is carefully dried. Perlsucht bacilli will be found to be very much larger than tubercle bacilli; in fact, they appear gigantic, according to the author, and the distinction between the two is easy. Another method consists in staining with carbol fuchsin and then treating the smear several times with a solution of picric acid acidulated with three or four drops of fifteen per cent. nitric acid. The picric acid solution consists of equal parts of a saturated aqueous solution of picric acid or of Esbach's solution, and absolute alcohol. The smear is then treated with fifteen per cent. nitric acid until it has a pale yellow color, is rinsed with alcohol, and is again stained with the picric acid solution. For the details of these and other methods reference must be made to the original.

Pathology of the Heart Beat.—Bönniger contributes an article on this subject in which he says that simultaneous contraction of the auricles and ventricles as evidenced by systolic venous pulse is a not infrequent condition. Systolic venous pulsation is seen in cases of tricuspid insufficiency, but the condition described by the author is independent of any leakage of this sort. The customary concomitants of tricuspid incompetence such as early and severe edema, dilatation of the veins, and pulsating liver, are absent, though the cardiac action is likely to be very irregular. It is possible to recognize the condition by observation of the heart with the fluoroscope, and the absence of the congestive and other accompaniments of tricuspid lesions is characteristic. The significance of the phenomenon lies not so much in its effect on the circulation, since this often seems to be but slightly affected, but in the province of treatment, as the use of digitalis appears to be undesirable and often serves only to increase the irregularity and tachycardia.

French and Italian Journals.

Treatment of Angiomata and Nævi.—Zimmern in speaking of the treatment of these blemishes says that electrolysis by the method of electropuncture is sometimes used. In nævi with visible telangiectasis this treatment at the end of a period sometimes long, sometimes short, produces very satisfactory esthetic results, according to Brocq. Negative monopolar electrolysis is used. Recently Bergonié has proposed to treat smooth vascular nævi by high-frequency currents. Brocq considers that in the case of prominent vascular tumors, that is, erectile tumors, electrolysis constitutes a wonderful treatment. Electrolysis in the treatment of angiomata is a definite operation, sure and applicable to all varieties of cavernous angiomata, small, grave, circumscribed, diffuse, or those invading neighboring tissues. The writer then describes with illustrations the technique of the treatment for these lesions.—*Journal de Médecine de Paris*, December 27, 1906.

Scopolamine in Surgery and in Obstetrics.—Albert Laurendeau in a recent work on this subject advises a dose of 1.50 grains of the hydrobromate of scopolamine combined with 1/5 of a grain of morphine to be given to adults by means of hypodermic injections in the lower extremities. This injection may be given if necessary three times in all at hour and a half intervals. This medication is not meant to replace chloroform absolutely. The toxic coefficient of scopolamine-morphine is less than that of chloroform. Its manipulation is more easy, and its method of administration is more definite. It may be employed in cases of tuberculosis, of heart lesion, and of cachexia. These drugs are advised in the case of patients who are subject to vomiting, in cases in which the intervention is of long duration, in cases in which surgical intervention is followed by severe pain, in first aid work, and in obstetrics. One dose suffices to abolish all consciousness and memory for several hours.—*Le Journal de Médecine et de Chirurgie, Montréal, Canada*, December 29, 1906.

Transparence of the Cranial Bones to X-Rays.—C. Luraschi began in 1904 a study of the results to diagnosis and prognosis of the application of the *x*-ray to the bones of the skull. He finds that it is of value in locating disease of the various sinuses, as the frontal, mastoid, and the antrum, and in detecting tumors of the brain. The rays are of more value in the examination of thin bones, such as those of children. It is possible to distinguish the layers of skin, skull, and dura mater by photography. By radiography one can distinguish the thickness of various parts of bones, and localize foreign bodies, such as projectiles. They are of the greatest use to the rhinologist and the dentist.—*Giornale di Elettricita Medica*, September and October, 1906.

Experimental Pancreatectomy in the Dog.—At the meeting of the Biological Society, November 24, 1906, Sauvé showed a dog on which he had practised fifteen days previously a duodeno-gastro-pancreatectomy. From the results of experiments which this investigator has made on a series of ten dogs, he concludes that it is impossible to remove the entire pancreas of the dog without removing the duodenum also. If the duodenum is not removed it will slough. Gastro-duodeno-pancreatectomy in the dog may be practised at one sitting, at the same time with the complementary operations for reestablishing the course of the chyme and of the bile. The question of glycosuria which, after pancreatectomy, lasts till death, is still, in spite of current opinion, unsolved. The negative experiments of Pflueger and a case of total pancreatectomy in a man corroborate the reports of the author.—*La Presse Médicale*, December 1, 1906.

Aberrant Goitre.—Reynier reports two observations of tumors, the one located under the angle of the jaw in the submaxillary region; the other adherent to the external surface of the vessels over the sternomastoid and which projected into the subclavicular triangle. Careful histological examination of these cases left no doubt as to the thyroid origin of these tumors. It showed conclusively that the thyroid origin of certain branchial tumors can no longer be denied; and it also supported certain recent embryological data in the explanation of their development. According to Delbet, it is an important fact that epitheliomata of the neck develop from epithelial débris which have existed since the embryonic period. Histological variation matters little since it is now known how closely connected are the branchial clefts, the lateral thyroid invaginations, and the thymic invaginations.—*Revue de Chirurgie*, December 10, 1906.

Book Reviews.

THE INTERNATIONAL MEDICAL ANNUAL: A Yearbook of Treatment and Practitioner's Index. Twenty-fifth Year. New York: E. B. Treat & Company, 1907.

WE find a number of subjects comparatively new in medical science, and for the most part not yet admitted to the text-books, treated fully and intelligently in this excellent review of the year's progress. Among the titles of the chapters, giving an indication of their contents, are: "Serum-therapeutics," "Opsonins and Vaccine Inoculations," "Cancer," "Diseases of the Ductless Glands," "Chemical Pathology of Gout," "Bier's Treatment," "Spinal Surgery," "Colored Urines Tested by the Spectroscope," "Dictionary of Treatment," "Examination of the Blood," "Electrotherapeutics and Radiotherapeutics," "Syphilis," and "Diseases of the Sinuses." The two last named are excellently illustrated, four plates, two colored, being devoted to the illustration of the spirochete of syphilis. Indeed, the illustrations throughout the work are very good; there are 28 plates and 60 pictures in the text. The contributions number thirty-five. The reader of medical periodical literature, in other words the educated and progressive physician, will find what he has read and studied from week to week through the year admirably summarized in this volume and put in a form where it is easily accessible for review or occasional reference.

THE NEW HYGIENE. Three Lectures on the Prevention of Infectious Diseases By ELIE METCHNIKOFF, Author of "The Nature of Man," with Preface by E. RAY LANKESTER. Chicago: W. T. Keener & Co., 1906.

THESE are the three Harben lectures delivered by Dr. Metchnikoff before the Royal Institute of Public Health in London last year. In the first lecture, "The Hygiene of the Tissues," the protective influence of the phagocytes is discussed in the light of the new impetus given to the humoral theory of immunity by the opsonic doctrine, and the conclusion is reached that, whatever may be the value of the opsonins in preparing microorganisms for destruction by the leucocytes, it is, after all, the latter which are the active and essential agents in the defense of the organism against the invasion by disease germs. The lesson of this is the importance of strengthening the phagocytes in their struggle against the host of pathogenic bacteria.

The second lecture, "The Hygiene of the Alimentary Canal," treats of the entrance of pathogenic bacteria into the blood by way of the digestive tract after their introduction therein with food. The lesson of this is that food should not be eaten raw, since in this way disease germs, but especially the ova of intestinal parasites, may be introduced. These helminths, though perhaps harmless in themselves, facilitate the passage of bacteria into the blood by wounding the intestinal mucous membrane.

The third lecture, "Hygienic Measures Against Syphilis," recounts the efforts that have been made, and are still being made, with the hope of ultimate success, to arrest syphilitic infection after inoculation with the virus of the disease.

M. Metchnikoff is not only a scientist and an original thinker of the first order, but also possesses the gift of a pleasing literary style, by which he is enabled to impart to others the knowledge he has gained by experimentation. These lectures will be found of absorbing interest not only by medical men but by those of the laity as well who have more than an elementary knowledge of physiology.

PRACTICAL AND THEORETICAL ESPERANTO. A Handy Textbook for Beginners and Advanced Students, for Self-Instruction and Teaching Purposes. Containing Elementary Grammar, Formation of Words, Complete Syntax and Exercises. By Dr. MAX TALMEY. New York and Boston: Universal Language Publishing Co., 1906.

THIS is, so far as we know, the pioneer instruction book for Esperanto written by an American. The author must have had considerable experience in language teaching, for he presents his subject in a way which shows that he knows the needs of the student. The exposition of the formation of the language is simple and most intelligible and the very questions which would naturally arise in the mind of the beginner are all answered clearly and distinctly. In a language which has not the authority of cultivated speakers, using their native tongues to support it, the question of pronunciation is perhaps the most difficult. Without absolutely fixed rules, illustrated, in the grammars for the use of different nations, by references to the established laws of pronunciation in the respective vernaculars, a confusion fatal to the employment of the language as a means of oral communication must arise. The author has recognized this necessity and has made the section on pronunciation very complete and explicit. Unfortunately, however, no two authorities which we have consulted, and we have compared for this purpose six or eight grammars by English, French and German authors, agree on this point. Even in the series of articles on Esperanto now running in the *North American Review*, the two sections devoted to the pronunciation are mutually contradictory on various points. Dr. Talmey also shows, in his discussion on the subject, that very marked differences exist, and the authority of even the creator of the language, Dr. Zamenhof, is rejected by him. If such a lack of uniformity in pronunciation exists at the beginning, what must the confusion become as Esperanto spreads among different nations, each with its own tradition of the value of the various letters. The next Congress of Esperantists should devote itself to the adoption of some absolute and immutable standard of pronunciation if they would save their language from meeting the fate of Volapük.

DISEASES OF THE STOMACH AND INTESTINES. By BOARDMAN REED, M.D. Second Edition. New York: E. B. Treat & Co., 1907.

THE whole digestive tract practically being one organ, Reed thought best to describe the diseases of the stomach and intestines in one volume. The writer greatly enhances what is of value to the practitioner and is thereby guided by his own large experience. The physical methods of treatment are discussed at great length. According to Reed massage acts beneficially in conditions accompanied by a diminution of gastric secretion, while it is harmful in hyperchlorhydria. Reed says: "Considering the serious and often disastrous results to health that may come from hyperchlorhydria with its train of intestinal and nervous symptoms, and the readiness with which it can be greatly increased by massage of the abdomen, this powerful remedy should be prescribed with great carefulness and with more exact dosage than is now customary; and it needs to be remembered that in many neurasthenic patients with a tendency to excessive secretion of the gastric glands, even very moderate massage over the abdomen can set up this troublesome condition with a resulting aggravation of the constipation, as well as of the insomnia and all the nervous symptoms."

Rest treatment the writer recommends in the following words: "By rest patients are not only given the absolute rest in bed which is grateful to many of them, but, what is far more important, are thereby removed at once from numerous actual or possible disturbing causes—from mental strain, overexcitement or overexertion of any kind, nagging cares and worries, the temptations of dietetic indiscretions as to food or drink, late hours, with insufficient sleep and dissipation of whatever form, whether downright vicious and under the ban or fashionable and approved by society, no matter how unhygienic. All such dangers, known and unknown, are cut off at one blow by the rest treatment, and many of them are particularly efficient causes of hyperchlorhydria.

The illustrations accompanying the text are numerous and excellent. As a whole the present book can be highly recommended.

THE CHEMICAL INVESTIGATION OF GASTRIC AND INTESTINAL DISEASES BY THE AID OF TEST MEALS. By VAUGHAN HARLEY, M.D., Edin., M.R.C.P., F.C.S. Professor of Pathological Chemistry, University College, London, and FRANCIS W. GOODBODY, M.D., Dubl., M.R.C.P. Assistant Professor of Pathological Chemistry, University College, London. London: Edward Arnold. New York: Longmans, Green & Co., 1906.

THE diagnosis of diseases of the alimentary tract is now so largely founded on the purely objective results obtained by means of chemical and microscopical examinations of material obtained from the stomach or intestine that it is not astonishing to find a work of 250 odd pages devoted purely to the former of these modes of investigation. The first eighty-eight pages contain a thoroughgoing discussion of the methods of gastric analysis and the remainder of the volume is given up to the subject of intestinal disorders. How important the laboratory methods have become in dealing with cases of this sort is evidenced by the fact that the description of the chemical examination of the feces alone covers nearly a quarter of the book. The use of test diets in the investigation of the feces is described and suitable diets are suggested. The microscopical and bacteriological aspects of the subjects under discussion are not taken up, as they have not been especially studied by the authors; but although the work is not primarily a clinical one, this phase has received sufficient consideration to make the text full of interest to the practitioner as well as to the laboratory worker. The one subject that seems to have been rather inadequately handled is that of occult hemorrhages, and some of the more recent tests for blood in the stools or stomach contents are not mentioned. The book is distinctly an interesting and useful one.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Regular Meeting, Held February 21, 1907.

First Vice-President, Dr. Robert Abbe, in the Chair.

This meeting was held under the auspices of the Section of Medicine.

Nitrogenous Metabolism in Typhoid Fever.—Dr. James Ewing read this, the opening paper of the symposium on typhoid fever. He said it had long been known that typhoid fever, rather more than other continued fever, was marked by a very high urinary nitrogen excretion, but the partition of this nitrogen and the bearing of variation in the forms of nitrogenous compounds excreted in the urine upon the pathology of this disease had received very scant attention. The total nitrogen excretion in urine and feces in typhoid had recently been studied in detail. The fecal excretion had been found to be relatively small, forming only 10 per cent. of the total nitrogen elimination. During the active febrile period and sometimes continuing into convalescence there was a pronounced loss of nitrogen, excretion exceeding ingestion by as much as 10 grams daily, the loss diminishing as the fever subsided. Since they were able to limit this loss to some extent by supplying nitrogen-free diet, they argued at length that the excessive nitrogen elimination of typhoid fever was not evidence of toxic destruction of cell proteids, but a result of simply hyperactivity of the metabolic functions. The present study was undertaken in 1905 as a control for the interpretation of results obtained by Wolf and himself in the investigations of the urinary nitrogen in the toxemia of pregnancy. It was also suggested that typhoid fever, especially in the later stages, was largely an autointoxication. It was pursued also in the hope of finding some correlation between changes in the urinary nitrogen and histological changes in the liver. The results were not without interest. The analytic methods employed were those described in a recent article by Dr. Wolf and the writer. Appended were reports of the analyses of seventeen cases, and the most obvious interest was in the relation of the urinary nitrogen and its partition to the clinical symptoms. The records showed a total urinary nitrogen excretion reaching 27.40 grams on the thirteenth day of a moderately severe case, but averaging considerably below 20 grams. With a restricted milk diet of these patients, this large percentage of nitrogen must signify consumption of tissue proteids and a marked loss of nitrogen on balance. The total nitrogen varied with the temperature, diminished in defervescence, when nitrogen retention began. The more favorable the condition the higher was the percentage of urea nitrogen. In severe stages it usually ran below 80 per cent., when 12 to 20 grams of N. were excreted; while in some cases which recovered it was found below 70 per cent., and even as low as 60 per cent. A ratio below 70 per cent. seemed to indicate a grave condition. Sharp increases in this ratio were very favorable signs; a rapid decrease, 82 per cent. to 67 per cent., and 80 per cent. to 60 per cent., was shortly followed by the death of the patients. In some instances the urea ratio seemed to be a better index of the patient's condition than was the temperature or the pulse. In two fatal cases the ammonia ratio reached 9 per cent. and 10 per cent. and in one fleshy woman severely ill it was found at 11 per cent. The present indications did not indicate that acidosis was a prominent feature of typhoid fever. Even the highest figures observed indicated only moderate grades of acidosis, especially for patients on a restricted milk diet. Brugsch had claimed that one of the chief causes of acidosis, when the system was unprotected by food, was the burning of the body fats, and the comparatively low ammonia excretion in typhoid fever when there was extensive consumption of tissue proteids was consistent with this view. In typhoid fever the total ammonia did not exceed the figure established by Folin, about .7 grams. The acetone bodies were not estimated in this series. A fall in the urea nitrogen was regularly accompanied by a corresponding rise in the rest-nitrogen. In severe stages of the disease the rest-nitrogen ran between 15 per cent. and 20 per cent. and in three fatal cases it rose above 20 per cent., once to 41 per cent. In two cases a sudden rise in the rest-nitrogen with a fall in the urea preceded the appearance of albuminuria. The following points of clinical interest appeared. Urea ratios below 70 per cent. and rest-nitrogen above 15 per cent. belonged to the severer stages and types of the disease. Rapid falls in urea with rises in rest-nitrogen occurred at unfavorable times in the disease. The ammonia nitrogen tended to run comparatively low, but in fatty subjects, or severe cases, or before death, it might rise to 10 per cent. or more of the total nitrogen. The character of the nitrogen partition in typhoid fever seemed to show some dependence upon, or relation to the lesion in the liver. In typhoid fever the liver, as a rule, showed some intense granular degeneration and usually focal necroses. Fatty degeneration was not prominent. If the final synthesis of urea was largely a function of the liver, the severe damage to the liver might be expected to yield for a time a low percentage of urea in a high total nitrogen output. The absence of extreme acidosis in typhoid fever accorded with the usual condition of the typhoid liver. The changes in the urine in fatal typhoid fever were very similar to those in acute yellow atrophy, and the occurrence of acute yellow atrophy as a termination of typhoid fever was not extremely rare. The results showed that the disturbance of nitrogenous metabolism was very similar to that of other infections and in some intoxications which were not of bacterial origin. Since this disturbance of metabolism was of a type which seemed never to occur without abnormal symptoms, there was reason to believe that it was partly responsible for these symptoms. Hence the conclusion was reached that in typhoid fever and other infectious diseases an important part of the morbid process consisted in a disturbance of nitrogenous metabolism which was very similar in type to that seen in pure autointoxications, and which therefore was not directly connected with the toxins of the invading bacteria. The excessive nitrogenous metabolism of typhoid fever was not the specific effect of the action of the endotoxins of the typhoid bacilli, but represented hyperactivity of a normal type associated with the fever. Wolf had pointed out that bacterial endotoxins were much alike in their actions and affected chiefly the nervous system. The central phenomena expressed of the disease resulted from the course which the metabolic activities of the organism took in reaching an equilibrium and effecting a cure. What they saw of typhoid fever was not merely the entrance and destructive effect of the typhoid endotoxins, but the burning of 30 pounds of tissue proteid in three weeks. Hence in studying the nitrogenous metabolism they were obtaining information about one of the fundamental processes going on in the diseased organism.

Dr. C. G. L. Wolf said that Dr. Ewing, in presenting the results of the investigations of typhoid fever, had endeavored to show the practical results which had been obtained, and the work suffered from its fragmentary character, as Dr. Ewing had remarked. Work of this kind, to be of the greatest value, must at first be done under exceptionally favorable conditions. The analytical technique should be as perfect as possible, and by that he meant the entire exclusion of the so-called clinical methods, such as the hypobromite method for urea, and the various purinometers, uricometers, and instruments of that sort. These various contrivances were not to be relied upon, any more than methods depending upon the centrifuge were of any value in the quantitative estimation of albumin, chlorides,

sulphates, and phosphates. But even with perfect technique, the task was not half completed. The importance which attached to the complete collection of a 24-hour specimen of urine could not be too strongly insisted upon. Furthermore, he said he was convinced that the patient should be placed on an accurate standard diet, of which the nitrogen content and the calorific value were accurately known. The diet should preferably be free from purin compounds. It was not in the least difficult to choose a diet of this sort, which would be suitable for almost any disease. He said he could speak with a certain amount of authority on this point, for in the work which Dr. Alexander Lambert and he had done in the metabolism in pneumonia they had obtained what they were inclined to believe were important data, which could not have been procured had the patient been allowed a diet which varied from day to day. It also seemed to him that a very careful clinical daily report would help to clear up many of the metabolic vagaries which were encountered in the examination of urines of this type. He trusted that the time would come when as a result of the accurate study of metabolism they should be able to substitute simpler methods, which might be used by clinicians, independent of the chemical laboratory; but the time had not yet come, and appeared to be at some distance. He thought he might safely say that anyone who would take up a single affection, such as those of the kidney, the liver, the anemias, and the various infectious diseases, and work out a few carefully selected cases on the lines which Dr. Ewing had laid down, would obtain results of distinctly permanent value.

The Management of the Intestinal Tract in Typhoid Fever.—Dr. Walter B. James read this paper, in which he considered briefly the feeding, the nursing, the general management, and the treatment of complications. He confined his remarks to the consideration of a few principles underlying the general treatment of the digestive system in typhoid fever.

Dr. George L. Peabody called attention to one difficult part of the problem, the management of the stomach. It had happened to him to have patients brought under his care who had been under no medical care at all, but under the care of relatives or friends, and their stomachs had been rendered irritable by bad feeding, obstinate vomiting being the early symptom. Even in the best managed cases obstinate vomiting occurred early in the disease. In this connection the first thing to do was to give the stomach a rest, and postpone introducing anything in it for twelve or more hours. He applied counter-irritation to the epigastrium, such as strong mustard paste. If the vomiting persisted, he advised against temporizing longer, but resorting to lavage. When he began feeding he used the utmost caution. If the vomiting was not checked within twenty-four hours, he used lavage. He said that Dr. James had referred to the unsatisfactory efforts made to regulate the amount of food taken by the number of calories we knew the patient should require. We could tell the number of calories required in health, but when there was such an altered metabolism as occurred in fevers, it was hard to say how many should be had. A patient weighing 120 pounds should receive 1,925 calories a day during health. But when there was an increased activity, and, therefore, increased metabolism, the patient should receive more. If milk alone was given, five or six pints would be required. Therefore, he agreed with Dr. James in his statement that milk alone was not a suitable diet for these patients. The number of calories could be greatly increased by giving alcohol in any form. Eggs helped materially. There were various modifications of milk that he was in the habit of using, such as koumiss, or matzoon. Clear soups were given throughout the disease; they stimulated the heart and the appetite, were agreeable and palatable. Water should be given in abundance. Beef juice was highly acceptable to the patient. For many years he had been in the habit of feeding the patients solid food if they became hungry. He was particularly fond of giving ice-cream in all stages of the disease. Constipation was best met by giving enemata. The presence of constipation was no evidence of the absence of ulceration, nor was diarrhea an evidence of the presence of ulceration; the latter was evidence only of a catarrhal condition. He had never known of a case of perforation caused by the use of cathartics. He never treated the diarrhea at all, unless there were more than three or four movements a day. If the patients had more than that number a day, it exhausted them; then he usually gave bismuth or opium, especially the aqueous extract. Meteorism was a serious symptom; when due to gas in the large intestine it was best relieved by the rectal tube, but not a large one. A catheter the size of a lead pencil was large enough. He believed still in the value of turpentine for the treatment of meteorism, administering 10 minims every three hours; this will often soften the abdomen and lessen the tension by reducing the amount of gas. Occasionally turpentine stupes would aid, but not often. There was not much to do for intestinal hemorrhage; place the bleeding part at rest by placing the patient at rest. Surgery was of no avail in intestinal hemorrhage. But in cases of intestinal perforation, nothing but surgery would avail, and only with promptness.

Dr. W. Gilman Thompson wondered what had become of the "gurgling and tenderness in the right iliac fossa," so much spoken of in the earlier text-books on medicine. He could not recall a case presenting gurgling and tenderness in the right iliac fossa, in cases of typhoid fever. He had not even seen those symptoms in late years; it was a striking fact that this pair of symptoms had practically gone out of date, probably owing to better methods of feeding. He did not believe that there was any disease in which so much routine treatment was recommended as in typhoid fever, and the more he saw of typhoid fever the more convinced was he that one could allow a great deal of latitude in treating the different types of the disease. When the soldiers came back from Santiago, turned loose on furloughs, with high temperatures and typhoidal stools scattered all over the country, from the 200 cases of typhoid fever then seen he had learned how much such patients could stand; it was surprising how many got well. Of course, they were all young and in fair health, but there was a high toleration of the human system for that disease. Of late years he had been treating typhoid fever patients more liberally in regard to diet. He gave a milk diet so long as it agreed. When the tongue became coated and there was a distaste for milk, he believed something else should be given. He gave liberally of beef and orange juice, etc. The great danger from meteorism was from stretching the gut and so causing perforation. When the gut was distended with gas the lesions could not heal. He was not accustomed to withhold food as Dr. James did in those cases. He believed there was a field for the use of drugs in cases of tympanites. There was nothing in the name "intestinal antiseptics," but there was something in intestinal antifermentatives. He gave salol and creosote in coated pills which did not dissolve in the stomach; they were dissolved in the intestine only and aided in keeping down meteorism. When the stools became foul and offensive, and there was diarrhea, and a tendency to tympanites, there should be proper attention to the regulation of the diet and cleansing the lower part of the bowel. When the stools were fetid, the absorption of food stuffs was added to the toxemia of the typhoid fever. He believed in giving turpentine internally, as well as externally. One should endeavor to keep down the tympanites, which was more to be dreaded than hemorrhage. It was well to feed typhoid fever patients early in convalescence with some solid food. If a relapse occurred the patient then would be better able to bear the disease again than if

he had been on an exclusive diet. He never had seen a relapse due to the giving of food. Ten per cent. of typhoid patients would have relapses no matter what the diet was.

The Treatment of Typhoid Spine.—Dr. Virgil P. Gibney read this paper. He said that the term "typhoid spine" was first suggested in 1889, when it was distinctly stated that it carried with it no pathological commitment. A suggestion was made, based upon seemingly good foundation, that a periosteal lesion, inflammatory in character and caused by the presence of the typhoid bacillus, was in all probability a lesion that could be accepted. Soon after, other reporters recorded cases that presented a fixed deformity, and the term "spondylitis" was employed to designate a destructive lesion in the bodies of the vertebræ resulting in deformity, such as one got in Pott's disease of the spine. Again, the term "neurosis" was invoked as explaining cases where no deformity existed. An osteoarthritis, posttyphoidal and involving the transverse processes and lateral masses, as well as the articular borders of the vertebræ, was believed by some to be the prevailing pathological condition. He referred to Thomas McCrea's paper on "Typhoid and Paratyphoid Spondylitis with Bony Changes in the Vertebræ," read before the Association of American Physicians in Washington, May, 1906 (see Medical Record, Vol. LXIX, page 897). A periostitis of the vertebræ naturally suggested involvement of the articular borders and the foramina of exit of the nerves, and the many cases already on record of bony enlargement were confirmatory of the theory first advanced as the primary pathological lesion. McCrea's conclusions were: "1. In certain instances of typhoid spondylitis there are certain definite bony changes in the vertebræ. 2. The general features of the condition suggest the probability of organic changes in the spine being a usual occurrence. 3. The similarity of the changes found in typical spondylitis and those found in spondylitis of other infections, especially arthritis deformans, suggest that the latter may be due to various infectious agents." It seemed pretty well established by a number of cases already on record that trauma played a very important part as a factor in the etiology. Dr. Gibney claimed to have had fairly good results in a reasonable length of time by resorting to fixation of the column, the avoidance of trauma, the free use of the Paquelin cautery, and the subsequent employment of well-directed massage and graded exercises. The value of the cautery as a counter-irritant had proved so valuable in his hands that he felt justified in recommending it above all others. The plaster-of-Paris jacket or corset had not proved so valuable an agent as had the simple Knight spinal brace or the posterior spinal assistant of Taylor. The crisscross strapping with Z-O plaster had been a valuable adjunct, especially in the milder forms of the disease. Where deformity existed it was necessary to wear apparatus for longer periods. He emphasized the importance of a clean-cut diagnosis made by a careful examination of the parts, by interpretation of the pains in an honest endeavor to determine whether the pains were radiating and due to pressure on a nerve, or whether they were boring pains of surfaces rubbed together, and after having made the diagnosis adopt methods of treatment that might be regarded as rational. In spinal lesions it was important to immobilize not only the parts involved but those contiguous thereto, above and below, and to get an accurate adjustment of the immobilizing apparatus. The Paquelin cautery was insisted upon as a regular line of treatment as long as tenderness and pain on movement existed.

Dr. T. Halsted Myers said that he had looked up the medical histories at St. Luke's Hospital and found that there had been 500 cases of typhoid fever in five years, and there was not one single case recorded of typhoid spine. There were some cases of periostitis, but in other locations than the spine. He urged the importance of diagnosis.

Dr. Leonard W. Ely said that the name "typhoid spine" seemed to be the best. While there might be a spondylitis present, and probably was, yet one never got abscesses, and the disease always terminated in an absolute recovery. All these cases got well. He invariably told his patients that, dating from the beginning of the trouble, they should be well in one year or eighteen months. Nobody agreed with Dr. Osler's statement that the disease was a neurosis. There was almost always a history of trauma. The use of the Paquelin cautery was of value in the convalescent stages, as well as in the active when there was the acute pain. The pain in the acute stage was sometimes terrible, and sometimes in these acute paroxysms morphine or anesthetics were required. Rest in bed, counterirritation, and later on the jacket or brace, was the treatment.

Stated Meeting, Held March 7, 1907.

The President, Dr. John A. Wyeth, in the Chair.

A New Section.—It was moved, seconded, and unanimously carried that a Section on Materia Medica and Therapeutics be organized in the New York Academy of Medicine.

The Typhoid Epidemic in Berwick, Pa.—Dr. J. H. Bowman of Berwick presented this paper, which was read by Dr. Charles F. Adams. He said that for two winters in succession Berwick had been visited by epidemics of typhoid fever. The epidemic of 1906-7 began in October, the first case having been reported on the 15th of that month; new cases continued to be reported until January 1, 1907. The total number of cases to March 1 was 114 and the mortality 9. It was noticed that by far the greater number of cases occurred in the rolling mill department of the local industrial plant, where on account of the great heat an abundance of water was drunk. It was also observed that in the last epidemic a greater number of women and children were ill than in the former. Berwick and its immediate vicinity had a population of 15,000 and was dependent for its water supply on several mountain streams and on the Susquehanna river. It was situated 41 miles below Scranton. The sewage of both these cities as well as that of Wilkesbarre and Pittston emptied into this river. Soon after the outbreak in the fall the water from the river was turned off and was not turned on again until February 15. The State inspectors examined the water from all sources but said that the presence of the typhoid bacillus could not be demonstrated. The water sheds were inspected but no source of infection was found. The dairies were also inspected, but failed to reveal any cause for the outbreak. With all these negative results the fact remained that the infection was so general and widespread that the cause, whatever it was, was conveyed by some general commodity, such as drinking water. The conclusions reached were that polluted water was the cause of the wide distribution of the typhoid germs. In all probability the first case resulted from the use of Susquehanna river water, drawing as it did a large volume of sewage from Scranton. These cases distributed over the general area of Berwick and its suburbs carried the infection into the mountain streams, so that although the river water was cut off the other supply had become infected. A concurrent epidemic of influenza which attacked a greater number of patients than in any year since the memorable epidemic of 1889-1890, diminished the normal resistance in these cases and made the subjects more susceptible to the typhoid infection.

The Typhoid Epidemic in Pittsburg.—Dr. J. F. Edwards, Superintendent of the Bureau of Health, Pittsburg, Pa., presented this paper, which was read by Dr. John A. Wyeth. He said that it must be borne in mind in the

study of this epidemic that typhoid fever had been prevalent continuously during the period of available statistics, or since 1873. Certain years or groups of years showed a high percentage as compared with others, but in no year had the mortality been low as compared with other American cities. The average mortality from 1880 to 1906 per 100,000 of the population was 107. The lowest rate was 55 per 100,000 in 1894, and the highest 158 in 1882. With the exception of these two years the highest rate was 141 per 100,000 in 1900. It was evident that a predominating etiological factor was at work continuously but with varying intensity for the past 36 years, and probably for a much longer period. The present high rate period began in 1899 as was shown by the following: 1899, 112; 1900, 141; 1901, 124; 1902, 130; 1903, 135; 1904, 140; 1905, 100; 1906, 130. These figures showed that the causative factor had acted continuously during the past eight years and to a greater degree than in any like period in the history of the city. The predominant cause was an infected water supply. It was fair to assume that other conditions at work elsewhere in conveying the disease were also at work here. The general water supply of the city was drawn from two intakes in the Monongahela river and two from the Allegheny river. The water was pumped directly into reservoirs, from whence it was distributed to consumers. Several wards in the city were supplied by corporations, one having its intake about one mile further up than that of the city. There is said to be some filtration here by means of a crib in the river bed. One ward was supplied by a corporation with water taken from the Monongahela from an intake above the others and last year instituted a filtration plant. It was the only ward supplied with filtered water and was at present practically free from typhoid. Both rivers had a large population in towns situated near the water's edge. The towns on the Monongahela were larger than those on the Allegheny and one would expect more typhoid in those portions supplied by that river, but such did not seem to be the case. In the past two years the rate per thousand had been about one-half as great in those wards supplied by the Monongahela as in those supplied by the Allegheny. The Monongahela had a very slight fall and a slow current and in low-water stages was said to be pumped out and put back five or six times during its course. One of these times it must run back through the sewers of the town. Both mines and mills introduced mineral acids into the water in sufficient quantities to make the water of the river acid during low water. In a laboratory experiment he had found that 5 parts of free sulphuric acid per 100,000 killed typhoid germs in one and one-half hours. It was said that the river reached 7 per 100,000 at times and near works might go 100 and more. The objection to the acid theory was that the river was alkaline during a good part of the year and typhoid fever was quite high on the South Side in August, when the water was low. Another corrigent of the Monongahela was the heating of the water by the works along its banks. Four large establishments pumped 178,000,000 gallons per day, five and three-quarter million gallons was to a certainty heated to the sterilizing point. Plants further up the river discharged proportionate volumes of sterilized water. The total was very large. During the winter of 1905-1906 typhoid prevailed in a number of boroughs above the city on the Allegheny river. The March thaw probably accounted for the grave increase in the number of cases reported in April. During the year a special effort was made to determine the influence of the milk supply. It could not be shown that any considerable number of cases could be traced to the milk supply. Since July of 1905 there had been a progressive increase both in cases and deaths which culminated in the sharp rise of April, 1906, when 820 cases with 78 deaths were reported. During the whole year there were 5,729 cases with 508 deaths. The ratio of deaths to reported cases was lower than in any other year and it was believed that this was partly due to the fact that more cases were reported than at any previous time. In general it might be stated that typhoid fever was more prevalent, all other things being equal, in districts where the standard of living was lowest. The incidence of cases during the last year exemplified this. Many people of the better classes did not drink raw city water. In congested districts there were greater opportunities for contact infection. A large percentage of cases occurred among immigrants from Austria, Hungary, Russia, and Italy. In conclusion, he stated that there was every prospect that Pittsburg's long and unenviable history as a typhoid city would soon close as a municipal filtration plant was nearing completion and it was hoped that this would greatly diminish the ravages of this disease, which destroyed on an average 300 of the most productive part of the population every year. Another promise of relief came from the State, which was looking toward the prevention of the further pollution of the streams throughout the State.

The Typhoid Epidemic at Scranton in the Winter of 1906-1907.—Dr. J. M. WAINWRIGHT, Chief Surgeon of the Moses Taylor Hospital, Scranton, Pa., read this paper. In regard to typhoid in Scranton previous to this epidemic he said that reliable morbidity reports were not at hand, but from the death reports it appeared that, while the disease had been constantly present, the total had not been very great as American cities went. The number of deaths was 21, 20, 11, and 25 respectively for the years 1902 to 1905. Estimating the mortality at 10 per cent., there had been during the past four years 200 cases. Reckoning the population at 75,000 to 150,000, Scranton had been heretofore comparatively free from this disease. Studying the conditions for the months previous to the outbreak, one saw that the fall rise in Scranton was not nearly as sharp as in other cities. So far as his hospital experience went, he did not notice the ordinary diarrheas which some authors had noted as precursors to typhoid epidemics. The epidemic broke from a clear sky and must have been due to a sudden and very large pollution of the water. It was interesting to note that in Philadelphia and Pittsburg, where typhoid was epidemic at all times, there was no fall rise. He described the Scranton water supply and presented a map showing that the larger part of the city was supplied by the Elmhurst reservoir. The principal tributary of this reservoir was Roaring Brook, which a few miles above ran through Moscow, a village of six to eight hundred inhabitants. This brook also ran through a hamlet of about 200 inhabitants. The Elmhurst water in previous years had been delivered over a spillway and allowed to run several miles into a storage reservoir. The distance from the inlet to the outlet in this reservoir was about 2,000 feet and the water displaced itself in from two to four days. For a number of miles a railroad ran near the brook and the railroad also ran close to the Elmhurst reservoir and another railroad actually crossed a small set bank. In October, 1906, this system was changed and the water was piped directly from the Elmhurst reservoir, cutting out the storage reservoir and taking the water from the bottom of the reservoir instead of over the spillway. According to Dr. Parke, from two to four times as many bacteria would be delivered in the water taken from the bottom of the reservoir as could be delivered over the spillway. About 50 per cent. of the bacteria would have died out in the passage of the water over the 2,000 feet of the storage reservoir. In October 20 cases were reported and in November 18. During the first week in December 11 cases were reported. This time suggested close connection with a heavy snowstorm on November 15, followed by warm rains, so that it was probable that a fecal accumulation of some time was washed into the reservoir suddenly at this time. It was a lamentable fact that the earlier cases were not reported and that proper action by the Board of Health was delayed for some days. The active period of the epi-

demic was from December 10 to January 10. Cases developing after that time were few and a number of secondary cases were due to direct communication, which could be easily traced. Considering the epidemic to have extended over December, January, and February, there was a total of 1,155 cases reported and 111 deaths; estimating the population at 115,000, one person was sick to each 100 of the population. A study of the map of the city showed very strikingly the distribution of the cases with reference to the Elmhurst water supply. The cases were very thickly grouped. In portions of the city having another water supply there were only 28 cases, and these were frequent visitors to that part supplied by the Elmhurst reservoir. He had been greatly impressed by the direct communicability of the disease. In 54 families there were two cases of the disease, in 22 of these the second person had been the attendant of the first case. In seven families there were three cases and in nine families four cases. Among these 16 families, in eight the attendant had been one of the secondary cases. It was interesting that in an unusual number of cases the secondary case was a child. The chief of the visiting nurses, Miss O'Halloran, who spent her time going from place to place fighting typhoid epidemics, considered that secondary infections were frequently due to other members of the family eating the portions of unusual delicacies which the patients left unfinished. It had been a great disappointment that, after a most painstaking search of the entire watershed by both city and State authorities, it was probable that the very multiplicity of possibilities had in itself been important in letting the exact cause escape unnoticed. The methods employed by city and State officials in fighting the epidemic did not involve anything new to sanitary officers. Close inspection was kept on the milk and no bottles were delivered to families. The spread of the disease from individual cases was combated by the visits of nurses under Miss O'Halloran. Circulars of instruction were sent to every house from which a case was reported and specific directions were given for the use of lime. He thought that the conclusions which they could draw from their lessons were: 1. All cases of typhoid ought to be promptly reported. When this was neglected grave danger signs would pass unnoticed. In going over statistics he had found a number of cities who had 20 to 25 per cent. mortality from typhoid on the face of reported cases. Health Boards, as well as physicians, were to blame for this laxity. 2. The advantages of municipal ownership. Under this system one at least eliminated the harm a private corporation might do during an epidemic in its efforts to safeguard the capital stock at the expense of further disaster to the people. 3. The numerous nuisances that had been maintained for years on this watershed showed the necessity of a rigid police inspection of the entire watershed by inspectors employed by and for the people and not by the water company. 4. Another safeguard which had been shown to be decidedly valuable was the frequent bacteriological and chemical examination of the water. The city laboratory of Scranton had not been equipped for such a purpose but soon would be. According to an authentic newspaper report there was a chemical analysis made by a private chemist early last fall which showed undoubted sewage pollution, and, if made by the city, intelligent people could have been warned that the water was unfit to drink. 5. In times of epidemic the water supply should be changed if possible. Hammer at the people the need of boiling water and milk and use all possible precaution to protect the milk supply. Prevent the spread of individual cases by visiting nurses, circulars of instruction, and the free distribution of one antiseptic. 6. Typhoid was to a very distinctly appreciable degree a directly communicable disease. 7. Physicians and sanitarians must recover from their habit of speaking of a certain amount of typhoid fever as "normal." Typhoid was a filth disease caused by imbibing more or less directly the feces of a sick man. The only normal amount for a civilized community was none at all.

The Bacteriology of the Blood in Typhoid Fever, Based on an Analysis of 1,600 Cases.—Dr. WARREN COLEMAN read this paper, which was the result of his own and Dr. B. H. Buxton's investigations. He said that in 1904 they had published an analysis of 604 cases of typhoid fever whose blood had been examined bacteriologically and 75 per cent. of those cases had shown the presence of the typhoid bacillus. In their earlier experiments they had used broth flasks, putting 2 or 3 c.c. of blood into each 100 c.c. of broth. Since August, 1906, they had used ox-bile, which not only prevented coagulation, but inhibited the bactericidal action of drawn blood. Their tests had confirmed the observations of Conradi, Kayser, and others. Their method was to take 90 c.c. of ox-bile, 10 c.c. of glycerin, and 2 grams of peptone. The mixture was distributed in small flasks containing 20 c.c. each and sterilized. Three of these flasks were used for each examination, about 3 c.c. of blood being run into each. The flasks were then incubated and the next morning streaks were made from each over the surface of litmus-lactose-agar plate. If the microorganisms were present they might be observed in five or six hours. If the growth did not redden the medium, and was found to be a bacillus resembling typhoid, it was tested for the Widal reaction with immune serum. In this way one could determine whether the case was one of typhoid fever within twenty-four hours from the time of drawing blood. Results showed that of the 1,602 cases 1,197, or 75 per cent., gave positive results. Since using the ox-bile method a much larger percentage of positive results went to show that the bacillus was present in the blood in practically all cases of typhoid fever. An analysis of the cases by weeks showed that of 224 examinations in the first week of the disease, 200, or 89 per cent., were positive. The earliest positive result was reported by Widal, who found the bacillus on the second day. Of 484 examinations made in the second week, 353, or 73 per cent., were positive. Of 268 examinations made in the third week of the disease, 178, or 60 per cent., were positive. Of 103 examinations made in the fourth week, exclusive of relapses, 15, or 26 per cent., were positive. The percentage of positive results was greatest, therefore, in the first week and steadily declined thereafter. Since using the bile method their results had been practically as successful as those of Busquet and others who had recovered bacillus from the blood of practically 100 per cent. of their cases. The various series of cases giving practically 100 per cent. of positive bacteriological results were too numerous to be accidental and compelled the conclusion that the typhoid bacillus was present in every case of typhoid fever and that failure to recover it was due to faulty technique. The diminishing percentage during the latter weeks of the disease did not indicate that the bacillus had disappeared from the blood in negative cases but pointed to a diminishing number of bacilli, whose presence imperfect methods failed to reveal. All investigators were agreed that the bacillus disappeared from the blood at or about the time that the temperature fell to normal. It was probable that the bacillus was present throughout the course of the disease, or at least within a day or two of defervescence. It seemed that in order to produce typhoid fever the bacillus must not have been present in the body and growing, but must grow in a situation whence it had free access to the blood. From work done on the absorption of the typhoid bacillus from the peritoneum and from the fact that in typhoid fever the lymph nodes and spleen contained such enormous numbers of bacilli, they concluded that in typhoid fever the bacillus first found its way from the alimentary tract to the lymphopoietic system, including the spleen, where it developed chiefly and from which it invaded the blood stream. They thought it doubtful if the bacillus multiplied in the blood, but believed that its presence there repre-

sented simply an overflow from the lymph organs. Hence the presence of the bacillus in the blood did not constitute a true septicemia. Absorption experiments showed that the destruction of the bacilli proceeded most rapidly in the blood. Hence they thought the disease was caused by the destruction of vast numbers of bacilli in the blood with the liberation of their endotoxins. The idea that the course of typhoid fever could be influenced by intestinal antiseptics was irrational because, after the invasion of the body proper by the bacillus, the battle ground shifted from the intestine to the blood. There appeared to be a definite relation in the evolution of typhoid fever between the symptoms and the bacillemia. The increased intensity of the symptoms in the earlier stages of the disease corresponded to the active growth of the bacilli. They invaded the blood stream in increasing numbers and were there destroyed. Then came the stationary period, when the ratio of growth and destruction appeared to be uniform. The steep curve period corresponded to a diminishing bacillemia, and defervescence to complete disappearance of the bacilli from the blood. They maintained that exclusive of convalescence, which was regarded as a period of repair, degenerative changes occurred only in the presence of active growth and destruction of bacilli. While bacilli disappeared from the blood at or just before defervescence, it was improbable that all the bacilli in the body had been destroyed, or relapses and post-typhoid inflammatory lesions would be impossible. The bacillemia apparently bore no relation to the type or severity of the disease except in so far as regarded number of bacilli. The bacillus was found in the blood equally, but not with the same persistence, in the mild as in the severe cases, and in the cases of short as well as of long duration. The importance of the definite establishment of the nature of these short duration cases could scarcely be overestimated from the epidemiological standpoint. The blood had been examined bacteriologically in thirty-three relapses, the typhoid bacillus having been recovered in thirty, or 90 per cent. of the cases. They now thought that a relapse was not due to reinfection with the typhoid bacillus from the intestine as the result of inestinal trauma brought about by dietary irregularities. He would not have it understood, however, that they were advocating a liberal diet in typhoid fever. They reiterated their former conclusion that the typhoid bacillus was always present in the blood before the serum reaction developed, for the reason that endotoxins must be liberated before the agglutinins could be formed. For the complete diagnosis of obscure cases by the serum reaction the tests must be made daily.

Dr. Morris Manges, speaking on the question of direct infection raised by Dr. Wainwright, asked if there could not be a direct infection from the sufferer to another rather than by the intake of polluted water. He referred to the case of a woman baker in Germany and all who used her bread developed typhoid fever. The typhoid bacilli were found in her feces; inasmuch as she prepared the food, and used the same toilet, the source of the infection was not hard to find. He recalled another case of a woman who had some intestinal complaint and fed only on a beef diet. The cook had a slight diarrhea, but the feces contained numbers of spirilla, thus showing the source of infection. Dr. Manges said that the work before Dr. Wainwright in Scranton was not an easy one if he wanted to find where the local focus was after the epidemic had passed away. In the Pittsburg epidemic the acidity of the river water was stated to have been 7 to 100,000, and yet the bacilli could not live for any length of time, it was stated, where the acidity exceeded 5. That showed Dr. Manges how fallacious the antiseptic action of the gastric juice on the typhoid bacillus was. He called attention to the unreliability of the number of cases reported, especially in villages, and recalled an instance where the Board of Health made an investigation and found that where but 8 cases of typhoid fever had been reported by physicians 72 cases had not been reported, and of these 53 occurred in children. In other words, there were nine times as many cases of typhoid fever as had been actually reported. With regard to river pollution in relation to the ice supply, Dr. Manges said that the ice companies were doing a great service; they were showing the enormous amount of pollution of the rivers, and when complaint was made to them they replied, "Why do you pollute the water where we get the ice?"

Dr. Sedgewick said that "food, fingers, and flies" was the summary of infection.

Dr. Libman discussed the paper read by Dr. Coleman.

Drs. Wainwright and Coleman closed the discussion.

MEDICAL SOCIETY OF THE COUNTY OF KINGS.

Stated Meeting, Held February 19, 1907.

Dr. Glentworth R. Butler in the Chair.

Medicine, Education, and Social Work; Their Necessary Relations.—Dr. Richard C. Cabot of Boston, Mass., read this paper. He alluded to the fact that at the exercises celebrating the opening of the new Harvard Medical School, President Eliot and Dr. Welch had summed up the achievements of medicine in the past and the directions of its future development. They had referred to the necessity of the study of animal diseases and to the importance of comparative pathology. The increased importance of the study of insects had also been alluded to. They had referred to the growth of preventive medicine and to the achievements of health officers. The pride of the listeners had been excited, yet the speaker, who had been one of them, had wondered whether the audience realized how small a proportion of sickness would be removed even if all infectious diseases were abolished. In the twenty-five years that had elapsed since Koch discovered the tubercle bacillus, the tendency had been to think of infectious disease as coextensive with disease in general. Prof. A. E. Wright had shown somewhat this same tendency. It was a fallacy that the bacteria were the cause of all disease, although all the recent medical heroes had won their victories in the treatment of infectious diseases. It had to be realized that there was a large residuum of diseases, constituting one-half of all disease, which would remain after all infectious disease had been abolished. The speaker had tabulated the 10,000 cases that had been treated in the outpatient service of the Massachusetts General Hospital during the past year, and found that from 30 to 40 per cent. of all these cases were functional in character. They included constipation, neurasthenia, insomnia, obesity, alcoholism, etc. It was probable that in private practice the proportion of functional disease was still greater, probably one-half of the whole. These cases were certainly not to be treated by means of antitoxins. They were to be combated rather by building up good habits and improving the environment of the patients. It was hence to be realized that medicine was necessarily bound up with education. By means of the latter were to be inculcated good habits of eating, sleeping, working, etc. This was to be accomplished through the agency of demonstrations, explanations, public lectures, reading, and other channels. The cooperation of schools, institutions, and sanatoria had to be enlisted. It was necessary to investigate the finances of the patient. It was sometimes necessary to take him out of his family or improve the family surroundings. This was properly the sphere of the social worker, but it was rightly also the sphere of the physician. It did not mean that the latter was to become a jack-of-all-trades. Drugs were not the only remedies for disease. Faulty habits and faulty environment were causes that had to be eradicated. In former years the prescription was the main thing handed out to the dispensary patient. Later on this

was supplemented by the list of printed directions and warnings. But it was common knowledge that the latter were rarely effective. One year ago the speaker had organized in the Massachusetts General Hospital a department of social work. He had become tired of seeing patient after patient who could not be reached by means of medicine and surgery. One of the first things done was to follow up these patients. The victims of tuberculosis were instructed how to build their platform and put up their tent on the roof, or if the latter was not available, how to sleep in the yard. It was frequently necessary to advise the patient to take a vacation, but no inquiry was made as to his means of doing so. If a father, he had his family to support; if a mother, she had the household to look after. The response of the patient to this advice was usually, "But I can't, doctor," and the latter responded by calling out, "Next patient." The department of social work thus served to fill the wide gap between good intentions and their fulfillment. Social work and education were therefore necessary factors if the physician was to do any real good to his patients. One-fifth of the patients in the dispensary and in private practice needed simply proper instruction in hygiene. The simple life which suited the needs of one patient would drive another to drink. There was also organized a hygiene class which was presided over by a graduate nurse. Another nurse was employed who gave her whole time to following up cases of infant feeding to their homes, and to instruct and direct mothers in the proper preparation of their infants' foods. Wherever was found a good physician there was found one who was actively engaged in some kind of educational work. Medical men wrote more than any other professional class. This was not merely for advertising purposes. There was a natural kinship between medical writing and teaching. The colleges, public schools, and lecture platform were the means through which the physician could reach the individual and the family. Public medical lectures had been established at the Harvard Medical School and were delivered every Saturday and Sunday. As an educator the physician had long been recognized; as a social worker he was only beginning to exercise his opportunity and privilege. There were two other fields through which the physician was to exercise his influence, namely, psychotherapeutics and public health. The speaker did not pretend to do more than to refer to these subjects in a synoptical way. In psychotherapeutics one dealt with the patient from his sociological aspects. There was the need of studying each patient's work, with the view of determining its effect upon him; whether it produced worry, internal friction, restlessness. Was it suited to his capacities or tastes? It was also necessary to consider the domestic and sexual relations of the patient. Was the patient stoical, cynical, complacent, fatalistic, reckless, etc.? The physician also had to reckon with his inheritance. The relation of the physician to his patient through the medium of the public health was a subject that had grown so fast in the past decade that it was a source of wonder whether there would be any private practitioners in the future. The medical inspection of schools was a recent development. In the schools the physician had put his hands upon disease in the most critical period of life. His advice guided the construction of public playgrounds, school houses, and the solution of problems of ventilation. Through departments of health the physician sought the prevention of malaria, diphtheria, etc. The free distribution of quinine and antitoxin was a natural corollary of the State's intervention. The foundation of free sanatoria, the regulation of dangerous trades, the enforced renovation of filthy slaughter houses, the abolition of dangerous house conditions, the control of venereal diseases, were all evidences of the public character of modern medical endeavor. One could not think of a single nameless profession of which medicine, social work and education were not branches. This trinity formed a striking contrast to the professions of conquest, namely, war, business, and athletics. War was usually business, and business was usually war. In medicine the aim was development. It was to heal by teaching and to teach by healing. Whenever medical work was good work it merged with that of the educator and the social worker.

Treatment of Chronic Heart Diseases.—Dr. Theodor Schott of Nauheim, Germany, read this paper. He said that twenty-five years had elapsed since the time when, apart from hygiene, there were only two means of dealing with chronic heart disease, namely, the enforcement of rest and the administration of digitalis. Particular attention had been paid to pathological anatomy and diagnosis, but treatment was neglected. During this quarter of a century three methods of physiological therapeutics had been developed. They were the Swedish gymnastics, Oertel's treatment, and the Schott treatment. For the sake of completeness the speaker next discussed the rôle of drugs in heart disease. There was a remarkable increase in the number of remedial agents. Digitalis was used either with or without digitonin or digitoxin. Sometimes its cumulative effect necessitated a resort to strophanthus. In the presence of a relaxation of the heart muscle, strychnine elicited strong contractions, but it soon elicited abnormal irritability, followed by a depression of the heart's action. Erythrol tetranitrate and nitroglycerine were valuable chiefly for their effects on the arteries. The salts of mercury, as calomel, were not strictly heart remedies. They influenced the heart indirectly through their diuretic action. Morphine failed to tone up the heart, but it was not to be discarded in the case of cardiac pain and oppression, in which a strong dose might be administered. The speaker next discussed the physiological methods of treatment. It was the Dublin physician, Stokes, who first favored mountain climbing in the treatment of heart disease. His views were forgotten until twenty-five years later, when Oertel took them up, with the addition of a restriction in the amount of liquids allowed to the patient. The principle of this restriction was that by means of it the circulation was facilitated. The Schott treatment granted that the heart was strengthened by climbing; but diet was an important accessory. On the other hand, diminution in the supply of liquids was not necessary. The composition of the blood was constant, irrespective of the amount of liquid that the patient took. The diet selected was that best adapted to maintain the nutrition of the patient. It was desirable to prevent the accumulation of fat and to cause an increase in the amount of muscle tissue. Experience showed that a rapid diminution in the weight caused bad effects. The mechanical part of the treatment aimed at a development of cardiac strength by means of an increased action of the muscles. The original treatment had been devised for fatty heart. The theories that had been advanced in favor of the Oertel treatment were for the most part erroneous. Instead of a low diet, the patient often required an abundance of food. Climbing was resorted to only after the heart had been strengthened by other treatment. Oertel gave an erroneous interpretation to the mechanical treatment. The use of Swedish movements had no scientific basis. The exercises devised by Zander were carried out independent of the position of the patient's body. They caused an increase in the musculature and an acceleration of the circulation. They required continual supervision, and a regulation of the resistance. Failures were frequent, for an exact determination of the resistance was difficult. The expense of the apparatus was another drawback. The speaker next discussed the method of physiological gymnastics. It was first introduced in 1872. It was then found that mineral baths were effective in rheumatism complicated with cardiac disease. The speaker's late brother had found that the physiological cure by means of mountain climbing had produced the best results. They had both found that the regulated baths had the same effect as the mountain climb-

ing- in toning up a weak heart. In this condition one dealt with the inadequacy of the heart to impel blood, which usually led to a dilatation of the heart. But not every dilatation caused a failure of compensation. Only the former kind of dilatation required treatment. If the dilatation was due to inability of the heart to contract, or to a valvular lesion, there was caused a congestion of the heart itself. By means of baths and gymnastics the heart was rendered better able to contract. There resulted hyperkinesis and hypertrophy, and an increased pressure in the arterial system. The heart was relieved of the overpressure due to excessive filling. The heart was made to beat more slowly and vigorously. These results were confirmed by others, and also by means of animal experiments. Some observers explained the action of the baths on the basis of a derivation of blood to the surface. In the speaker's opinion this view was not correct. Comparing the effects of the baths with those due to the mountain climbing, it was found that those due to the baths were not as strong, but were more enduring, while those due to the gymnastics were more marked, but were less persistent. They both caused a decrease in congestion and cyanosis, a reduction in the pulse, an increased diastole. In suitable cases, arrhythmia disappeared. The speaker cited the case of a patient fifty-two years of age, suffering from mitral insufficiency, associated with myocarditis and pulmonary emphysema. He had had two attacks of embolism of the lung and had congestion of the limbs. His condition was wonderfully improved by the combined balneological and gymnastic treatment. Percussion revealed the good effects upon the heart. This reduction in size was also shown by means of changes in heart tracings and by means of skiagrams. The defect in skiagrams was due to the impossibility of getting the patient into the same position each time. On auscultation there was a change in the cardiac sounds; weak sounds became more audible, and hitherto inaudible murmurs became audible. Diuresis became more potent through balneological treatment. The whole organism gained strength, venous congestion was diminished, and there was a greater volume of blood in the arterial system. Owing to the larger amount of blood in the coronary arteries, the nutrition of the heart muscle was improved. There was an increase in the amount of hemoglobin. The balneological part of the Schott treatment had been described by many observers, including Osler, Babcock, Anders, etc., and it was impossible to give more than the general rules for its application. It was an agent of great power and had to be practised with great caution and with frequent observation of the patient, for the clinical picture often changed. As the treatment progressed it was necessary to lower the temperature of the water. It was always advisable to observe the patient before, during, and after the bath. It was necessary to begin with brine containing 2 to 3 per cent. of sodium chloride, and the same percentage of calcium chloride. The bath was given at a temperature of 93° and lasted ten minutes. The temperature was not to be lowered during the first week. In the anemic patient it was prudent to give the bath at 95°. This temperature was not to be exceeded even with the combination of rheumatism and heart disease. In such cases cooler and shorter baths were more desirable. If the patient was quiet, he first experienced chilliness and then comfort, which was due partly to the heating and partly to the composition of the water. If the reaction did not occur within one minute, it was necessary to have the temperature of the water higher and kept so throughout the entire bath. Sometimes a second chilliness occurred. This was avoided by shortening the duration of the bath. If the baths were well borne, the sodium chloride, and particularly the calcium chloride, were increased. Later carbon dioxide was added. At first the percentage of this was weak. It was supplied from large underground basins containing 1,000 cc. of free carbon dioxide to each liter of water. Later the baths contained from 1,200 to 1,500 cc. of CO_2 to each liter of water. Still later there were administered effervescent running baths, the water flowing with a pressure of from 1 1-2 to 2 atmospheres and at a temperature of 90°, also containing 2,000 cc. of CO_2 to each liter. This was the strongest form of bath given. Most patients required an intermission in the treatment. The bath rarely exceeded twenty minutes in duration and was followed by a brisk rub. The patient then went to bed for one hour. Later baths were given cooler and were more prolonged. They also contained mother-lye, which consists of 40 per cent. chlorate of lime. It was supposed that the movable molecules of CO_2 penetrated the skin. The cure was best administered in the summer, and for mild cases it lasted from four to six weeks, and was followed by a short stay in a locality of moderate altitude. Severe cases required a treatment lasting several months. The winter cures were given in a warm southern climate. The Nauheim baths could be made artificially, either with the aid of the Nauheim bath salts, or with the aid of NaCl and $CaCl_2$ in proper proportions. The CO_2 is prepared by means of the interaction of HCl and $NaHCO_3$, the quantity of the last being at first 100 grams per bath, and later increased to 500 grams. The HCl had to be pure and evenly distributed, and the CO_2 was to be developed slowly, its evolution lasting one-half hour. The artificial Nauheim baths had come into general use. It was an erroneous view that only the CO_2 was the active ingredient. Good results were obtained by the gradual increase of all the ingredients. It was observed that unsatisfactory results were obtained with many patients owing to the inability to properly regulate the bath. Long experience was necessary to do this. It was important also that the patient should be relieved from family and business cares, and should be on a proper diet. Besides, the strongest baths could not be made artificially. The baths wielded their influence through the sensory nerves, while the graduated gymnastics acted through the motor nerves. The latter brought the antagonistic muscles into action. Each exercise was developed slowly and the resistance so adjusted as to permit freedom of respiration. The various muscles were alternately brought into use, and when the series were completed the exercises were gone over again. The movements comprised a great variety, involving the movements of flexion, extension, adduction, abduction, and rotation. It was not difficult to teach a person of intelligence to become a gymnastic director. It was an advantage to train a member of the patient's family for this work. One of the rules was not to grasp or impede any part of the patient's body. Another was that no new exercises were to be begun until the pulse became slower and the breathing more easy. Later on mountain climbing was to be resorted to. Its contraindications were aneurysm of the heart or of the larger arteries, arteriosclerosis, apoplexy, and embolism. In cases of cardiac excitation, tranquillity was secured in a short time by means of tapottement. Vibratory massage was also useful. Ice-bags were also effective in quieting the heart. For this purpose also electricity, more recently the sinusoidal currents, were employed. The diet was to be a mixed one, with the avoidance of stimulating beverages, and with precautions against a distended stomach. The use of tobacco was either restricted or entirely prohibited. The physician had to take account of the question of social stress, occupation, and marriage. In the face of the Schott treatment, scepticism had in large measure vanished.

Bleeding Hemorrhoids.—Chloride of calcium is recommended by Boas as a hemostatic in this condition. Every morning after the bowels have moved 20 c.c. of a 10 per cent. solution of this agent is injected into the rectum and retained for a little while. If the tendency to hemorrhage is pronounced, a second injection should be made at night. If the drug is not chemically pure it may produce burning, pain, and tenesmus.—*Therapie der Gegenwart.*

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Medical Board of Examiners of the State of Pennsylvania.

December 4 to 7, 1906.

ANATOMY.

1. Name the arteries through which blood would pass from the heart to the thumb and the veins through which it would return from the thumb to the heart.
2. Describe the formation of the palmar arterial arches, and give anatomical landmarks for location of the same.
3. Describe the bony relationships and landmarks of the elbow joint.
4. Describe the anatomical structure of the female perineum.
5. Describe the structure and anatomical relationships of the female mammary gland.
6. Describe the anatomical structures entering into the formation of (a) the internal and (b) the external abdominal rings.
7. What muscles are attached to the great trochanter of the femur?
8. Describe the appendix vermiformis; give its relations and the external landmarks of its location.
9. Describe the superior maxillary bone.
10. Describe the uterus and give its relations and nerve supply.

PHYSIOLOGY.

1. Define metabolism. Cite an example.
2. Enumerate four conditions to be observed in taking the pulse, and describe what each signifies.
3. Over what functions of the body does the cerebellum preside?
4. Describe the thermal and chemical changes in muscle, as the result of exercise.
5. How is respiration influenced by the nervous system?

CHEMISTRY.

1. What is hemoglobin; name some of its properties and give a chemical test for it.
2. What chemical reaction takes place when hydrogen dioxid is applied to sloughing wounds?
3. Describe a reliable test for the detection of free hydrochloric acid in gastric contents.
4. When testing for albumin in urine, how do you determine between it and other coagulable proteids?
5. When testing for glycosuria with Fehling's solution, how do you determine whether the reaction is that of sugar or some other reducing agent?

MATERIA MEDICA.

1. Classify electricity as a remedial agent, (*b*) and name the different forms useful in the treatment of morbid conditions, (*c*) describe how they are applied.
2. Name five vegetable and three mineral astringents, describing method of administration and dose in each instance.
3. Name and describe three antiseptics useful in internal medication.
4. Describe and classify the important active principle of each of the following drugs: Hydrastis canadensis, veratrum viride, and lumulus.
5. Write a complete prescription for a child of three years suffering with pertussis. (or) Discuss ergota, stating to what alkaloid or active principle it owes its therapeutic activity.

PATHOLOGY.

1. Describe the cardiac changes that occur in mitral stenosis.
2. Describe the alterations that occur in the respective coats of an artery which is the seat of endarteritis obliterans.
3. Describe two methods of wound repair.
4. Describe the pathological changes occurring in dry gangrene.
5. Describe the various forms of acute salpingitis

DIAGNOSIS.

1. Give a practical method of differentiating gastroptosis and gastrectasis.
2. Differentiate chronic parenchymatous nephritis and chronic interstitial nephritis.
3. Describe a case of tabes dorsalis and differentiate the condition from multiple sclerosis.
4. State the diagnostic symptoms of progressive pernicious anemia, and what changes in the blood aid in the diagnosis.
5. Differentiate acute synovitis and acute articular rheumatism.

THERAPEUTICS AND PRACTICE OF MEDICINE.

1. What are the symptoms of exophthalmic goiter, and what are some of the measures employed in its treatment?
2. What are the symptoms of abscess of the lung?
3. Describe the treatment of a case of sunstroke.
4. What are the symptoms of a typical case of acute lobar pneumonia?
5. Describe the treatment of a case of diphtheria.
6. Describe the symptoms and treatment of a case of acute tonsillitis.
7. Describe the symptoms of a case of chronic lead poisoning and outline a method of treatment.
8. What are the symptoms of poisoning by belladonna, and how would you treat such a case?
9. Name some of the indications and contraindications of ergot.
10. Name some of the most important uses of the preparations of opium.

OBSTETRICS.

1. Give the maternal causes of dystocia, and methods of treatment.
2. Give the most frequent causes of puerperal mammary inflammation and give treatment.
3. How would you deliver a child when face is presenting with chin posterior?
4. Describe the various methods of preventing infection during childbirth.
5. Give symptoms and treatment of placenta prævia.
6. Give the indications for version, and detail the operation.
7. Give the methods of resuscitation in the apparently still-born.
8. What symptoms would lead you to suspect threatened miscarriage?
9. Name the cause and give the diagnosis of pelvic hematocele.
10. To prevent laceration of the perineum, describe the proper method of delivering the head.

SURGERY.

1. Give the diagnosis and treatment of transverse fracture of the patella.
2. Describe the symptoms and give the treatment of the several forms of gangrene.
3. Define surgical shock and give treatment.
4. What are the symptoms of "Colles' fracture," and give treatment.
5. Describe a backward dislocation of the hip joint, and give treatment.
6. Describe the objective and subjective symptoms of strangulated inguinal hernia, and an operation for the relief of the same.
7. Give the symptoms and treatment of fracture of the vertebral column with compression of the spinal cord.
8. Enumerate the recognized degrees of burns, and describe the treatment for the second degree.
9. Describe surgical methods for treatment of stricture of the male urethra, with respective indications.
10. Give a minute description for the proper administration of ether for general anesthesia.

HYGIENE.

1. Name three diseases due to animal parasites, and tell how their introduction into the human system may be prevented.
2. What are the relative effects on health of altitude, sea air, humidity and sunshine.
3. What diseases are communicated by stools and sputum, and what are the best methods of prevention of communication?
4. Name three exanthematous fevers and describe a rational effective method of quarantine, giving the proper duration thereof.
5. Give the disadvantages and dangers of cold storage foods.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

Medical Board of Examiners of the State of Pennsylvania

December 4 to 7, 1906.

ANATOMY.

1. The *arteries* through which blood would pass from the heart to the thumb, are:—Aorta, innominate (on right side only) subclavian, axillary, brachial, radial, and princeps pollicis or dorsalis pollicis. The *veins* through which it would return to the heart are arranged in two sets:—(1) *Superficial veins*:—venous plexuses, superficial radial, cephalic, axillary, subclavian, innominate and su-

perior vena cava. And (2) *Deep veins*:—The venæ comites of the radial or deep radial, brachial, axillary, subclavian, innominate, and superior vena cava.

3. If the forearm is extended, the internal condyle of the humerus, the tip of the olecranon, and the external condyle will all be found on the same transverse line. In extreme extension the tip of the olecranon is slightly above the level of the condyles. If the forearm is flexed to a right angle, the tip of the olecranon is immediately below the condyles.

PHYSIOLOGY.

1. Metabolism is a name given to the entire series of changes that occur in a cell or organism during the processes of nutrition. It is of two kinds:—(1) anabolic, or constructive, and (2) catabolic, or destructive. The changes produced in the cells by the oxygen or nutrition conveyed by the blood, come under the class of anabolic changes.

2. (1) Its *frequency*: this gives the rate of the heart beats. (2) its *compressibility*: this denotes the force with which the heart is beating. (3) Its *tension*: this denotes the peripheral resistance, and also the state of the arterial walls. (4) Its *regularity* or *rhythm*: this denotes the regularity (or otherwise) of the heart's action in force or rhythm.

3. Muscular coördination, and equilibrium.

4. There is an increase in heat production, and consequently a rise of temperature. The muscle becomes acid in reaction, due to the development of sarcolactic acid; at the same time there is an increased consumption of oxygen, and more carbon dioxide is set free.

CHEMISTRY.

1. Hemoglobin is the coloring matter of the blood. It exists in the blood in two forms, as hemoglobin and as oxyhemoglobin. Chemically it is a protein; its molecule is very complex, and consists of the elements carbon, hydrogen, oxygen, nitrogen, iron, and sulphur. It is a crystalline solid, and is not diffusible. Hemoglobin is the means by which the oxygen is carried by the blood to the tissues. It readily enters into combination with other gases such as carbon monoxide, nitrogen dioxide, and hydrocyanic acid. It is soluble in water, insoluble in alcohol and ether.

Test. Mix some of the suspected liquid with a few drops of a saturated solution of sodium chloride, evaporate to dryness on a microscopic slide, add a drop or two of glacial acetic acid and gently warm; crystals or hemin or hematin will form on cooling, and may be seen under the microscope.

2. Oxygen is liberated and effervescence occurs. It acts as an antiseptic.

3. The phloroglucin-vanillin test:—The reagent is made by dissolving two grams of phloroglucin and one gram of vanillin in 100 cc. of alcohol. The test is made by taking a few drops of the filtered gastric contents and an equal quantity of the freshly-prepared reagent; these are then mixed in a porcelain dish, and evaporated over a water bath; in the presence of free hydrochloric acid a brilliant red color is produced, beginning at the upper border.

4. By using the four tests, as mentioned in the following table (compiled from Croftan):

	The Boiling Test	The Nitric Acid Test	The Potassium Ferrocyanide Test	The Biuret Reaction
Serum Albumin.	Positive.	Positive.	Positive.	Positive
Serum Globulin.	Positive	Positive	Positive. On the addition of acetic acid there is a precipitate which is redissolved on the addition of more acid.	Positive
Nucleo-Albumin	Negative	Positive	Positive. On the addition of acetic acid there is precipitate which does not redissolve on the addition of more acid	Positive
Albumoses	Negative	Positive. The precipitates formed in the cold disappear on heating, but re-appear on cooling.	Positive. The precipitates formed in the cold disappear on heating, but re-appear on cooling.	Positive
Peptones	Negative	Negative	Negative	Positive

5. On getting a positive result with Fehling's solution, a further examination should be made by the fermentation test. If fermentation occurs, it indicates the presence of sugar. The phenylhydrazine test may also be applied; it does not react with reducing agents other than sugar.

MATERIA MEDICA.

1. Bartholow classifies electricity among the agents used to excite the functional activity of the spinal cord and the sympathetic.

(*b*) Static or frictional, magnetism, galvanism, faradism.

2. *Five vegetable astringents*:—Hammamelis, dose of the fluid extract, ℥xxx. Gambir, dose, gr. xv. Kino, dose, gr. vijss. Hematoxylon, dose of the extract, gr. xv. Tannic acid, dose, gr. vijss.

Three mineral astringents:—Alum, dose, gr. vijss. Copper sulphate, dose, gr. 1/5. Silver nitrate, dose, gr. 1/5. Of the above silver nitrate is only applied locally as an astringent; all the others can be used internally or locally.

3. Phenol, creosote, and phenyl salicylate (salol).

4. *Hydrastis canadensis*: berberine and hydrastine, both alkaloids. *Veratrum viride*: jervine and veratrine, both alkaloids. *Humulus*: lupuline, an alkaloid.

5. ℞ Tincturæ belladonnæ ℥j
Extracti cannabis indicæ gr. jss
Glycerini ℥j
Tincturæ aurantii amari ℥ijss
Aquæ destillatæ q. s. ad ℥iv. Misce.
Signa:—Two teaspoonfuls every four hours.

The composition of ergot is indefinite; the chief constituents are:—Ergotine, ergotinine, ecboline, sphacelic acid, ergotinic acid, cornutine, tannic acid, and other substances. Most of these ingredients contract the blood vessels; the cornutine, in addition, is credited with the chief part in contracting the uterus.

DIAGNOSIS.

1. The stomach should be inflated; the diagnosis is then made by outlining the stomach. In both conditions the lower border of the stomach is depressed below the umbilicus. But in *Gastroptosis*, the upper border and pyloric end are also depressed, and the stomach assumes a vertical position; whereas in *Gastrectasis*, the upper border and pyloric end are but slightly depressed.

2. The following table is from Millard's work on *Bright's Disease*:

CHRONIC PARENCHYMATOUS NEPHRITIS.	CHRONIC INTERSTITIAL NEPHRITIS.
The urine is always albuminous.	Urine not constantly albuminous.
Urine usually scanty.	Urine usually abundant.
Dropsy and edema almost always occur.	Dropsy seldom or never present; sometimes slight edema.
Hypertrophy of the heart seldom exists.	Some hypertrophy of heart, with increased arterial tension, almost always present.
Specific gravity of urine usually higher than the normal. Urine darker and with less of a soapy appearance.	Urine generally of a light color and low specific gravity.
Uremic symptoms less frequent.	Uremic symptoms are met with in their most pronounced form, and in severe cases usually occur.
Epistaxis and cerebral hemorrhages rare.	Epistaxis and cerebral hemorrhages frequent.
Occurs most frequently before the age of forty.	Occurs most frequently after forty.
Blood corpuscles and connective tissue shreds more frequently found	Absent.
	Development more gradual, the health of patient often less impaired, and duration longer.
Casts more numerous and in greater variety; waxy, granular, fatty, and hyaline casts occurring.	Casts rare, the hyaline variety being most frequently met with.
Epithelia from the kidney and pus corpuscles more numerous.	Kidney epithelia and pus corpuscles scanty, and occasionally absent.
Urates and phosphates predominate; oxalates rare.	Oxalate of lime almost always occurs.
Albuminous retinitis rare.	Albuminous retinitis common.
Gangrenous erysipelas and phlegmonous swellings more common; also dyspepsia and anemia.	
Visceral complications not uncommon.	Visceral complications rare.
Atheroma of arteries rare.	Atheroma common.

3. In *multiple sclerosis* there will be found increased reflexes, a greater loss of muscular power, volitional tremor, nystagmus.

In *locomotor ataxia*, there are: lightning pains, loss of knee jerk, ataxia, but not much loss of muscular power, Argyll-Robertson pupil.

4. Pallor, indisposition to exertion, palpitation of heart, flabbiness of muscles, poor appetite, languor, edema, debility, hemic murmurs, water-hammer pulse, dyspepsia, diarrhea. The blood changes are:—great diminution in the number of red corpuscles, hemoglobin is relatively increased, the red cells vary considerably in size and shape, and there are present nucleated red corpuscles of all sizes and in varying numbers. The white corpuscles are either unchanged or slightly diminished in number.

THERAPEUTICS AND PRACTICE OF MEDICINE.

1. Tachycardia, enlargement of the thyroid gland, exophthalmos, and tremor are the cardinal symptoms. Other symptoms are:—pigmentation of the skin, edema and moisture of the skin, impaired nutrition, anemia, and mental irritability and depression.

Among the measures employed in its treatment are:—iron, digitalis, ergot, the bromides, rest in bed with application of ice bag over the heart or thyroid gland, electricity, thyroid or thymus extract, iodine, opium, section of the cervical sympathetic nerve, and partial thyroidectomy.

2. Chills, high fever, signs of a cavity or of general pyemia; the sputum is offensive and yellowish or greenish in color, and contains elastic fibers or fragments of lung tissue.

3. The first thing is to lower the body temperature. The patient should be put into a cold bath, rubbed with ice, and given a hypodermic of some active antipyretic; he should be wrapped in a wet sheet, and if necessary may receive ice water enemata. Further symptoms may be treated as they arise; for heart failure, digitalis and strychnine may be given hypodermatically; for convulsions, chloral or chloroform.

7. *Symptoms*:—colic, chiefly round the umbilicus; cramps in the flexor muscles, muscular paralysis (wrist drop); pain in some of the joints; blue line on the gums at the border of contact with the teeth; anemia; constipation; eclampsia and nervous symptoms may also be present.

Treatment:—The patient should be removed from the source of harm, personal cleanliness in every way must be enforced, a hypodermic of morphine (gr. ¼) may be given for the pain, then hot baths, Epsom salts, diuretics, electricity, iron, and strychnine are all useful.

8. *Symptoms* of belladonna poisoning:—In the first stage, that of delirium, there are dryness of the throat, thirst, difficulty of deglutition and spasms upon swallowing liquids, face at first pale, afterwards highly reddened, pulse extremely rapid, eyes prominent, brilliant, with widely-dilated pupils, complete paralysis of accommodation, disturbances of vision, attacks of giddiness and vertigo, with severe headache, followed by delirium, occasionally silent or muttering, but usually violent, noisy, and destructive, accompanied by the most fantastic delusions and hallucinations. Usually the urine is retained, and the body temperature is above the normal. The delirium gradually subsides, and the second stage, that of coma, is established, with slow, stertorous respiration, and gradually failing pulse, until death occurs from respiratory or cardiac paralysis, or sometimes in an attack of syncope during apparent amelioration. (Witthaus.)

Treatment:—The stomach should be washed out; pilocarpin may be given hypodermatically; morphine may be given cautiously during the period of violent excitement; cold applications to the head and artificial respiration are useful. There is no chemical antidote.

9. *Indications*:—To promote uterine contractions during third stage of labor; fibroids, menorrhagia, post-partum hemorrhage. Some forms of amenorrhea and dysmenorrhea, dysentery, arterial hemorrhage, congestive headaches, laxity of sphincters of bladder or rectum, hemorrhoids, aneurysm, diabetes, urinary incontinence, direct paralysis of the sphincter vesicæ, atonic spermatorrhea.

Contraindications:—In labor if the birth canal is not free, and the os uteri is not dilated.

HYGIENE.

1. (1) Malaria, (2) Trichinosis, and (3) Tapeworms.

(1) In the case of *Malaria*:—the destruction of all mosquitoes, or the prevention of inoculation.

(2) In the case of *Trichinosis*:—the meat (of the pig) should be thoroughly cooked; mere curing or smoking will not do. Further, there should be systematic inspection of the meat sold, and the animals should not be fed with the refuse of slaughter-houses.

(3) In the case of *Tapeworms*:—all meat should be thoroughly cooked, and vegetables should be thoroughly cleansed.

3. Diseases communicated by the *Stools*:—Typhoid fever, dysentery, cholera, intestinal tuberculosis. To prevent communication of these diseases, the stools should be received in vessels containing a disinfectant solution in greater quantity than the expected discharge. The whole should be thoroughly mixed and allowed to stand for at least one hour before final disposition.

Diseases communicated by the *Sputum*:—Pulmonary tuberculosis and pneumonia. To prevent communication of these diseases, the sputum should be received in vessels containing disinfectant solution, and kept covered when not in use. The contents of the vessel should be burnt, and the vessel washed with disinfectant solution. The patient should not wear either beard or mustache.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE.	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION		
Alabama*	W. H. Sanders, Montgomery	Montgomery	April	1–6
Arizona*	Ancil Martin, Phoenix	Phoenix	April	1
Arkansas*	F. T. Murphy, Brinkley	Little Rock	April	9
California	Chas. L. Tisdale, Alameda	San Francisco	April	16
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver	April	2
Connecticut*	Chas. A. Tuttle, New Haven	New Haven	July	9
Delaware	J. H. Wilson, Dover	Dover	June	18
Dis. of Col'bia	W. C. Woodward, Washington	Washington	April	11
Florida*	J. D. Fernandez, Jacksonville	Jacksonville	May	15
Georgia	E. R. Anthony, Griffin	Atlanta / Augusta	April / May	30 / 2
Idaho	J. L. Conant, Jr., Genesee	Boise	April	2
Illinois	J. A. Egan, Springfield	Chicago	April	17
Indiana	W. T. Gott, 120 State House, Indianapolis	Indianapolis	May	28
Iowa	Louis A. Thomas, Des Moines	Des Moines	June	—
Kansas	T. E. Raines, Concordia	Topeka	June	11
Kentucky*	J. N. McCormack, Bowling Green	Louisville	April	23
Louisiana	F. A. La Rue, 211 Camp St, New Orleans	New Orleans	May	9

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

California.—In order to obtain a duplicate certificate to practise medicine in this State, it will be necessary for physicians whose certificates were destroyed in the San Francisco fire to present to the Secretary of the Board an affidavit as to the loss of the original certificate. The applicant will also have to be identified. The fee for such certificate will be $1.00.

New York.—During the year ending July 31, 1906, the total number of candidates examined by all three boards was 1,035. Of those examined by the Regular Board: (1) 379 took the whole examination; of these 292 passed, and 87, or 22.9 per cent., were rejected. (2) 292 took the first half; of these 258 passed, and 4, or 1.5 per cent., were rejected. (3) 270 took the final half; of these 264 passed, and 12, or 4.3 per cent., were rejected. The rejections per topic for the academic year were as follows: Anatomy, 43; Physiology and Hygiene, 44; Chemistry, 27; Surgery, 41; Obstetrics, 46; Pathology and Diagnosis, 40; Therapeutics Practice and Materia Medica, 10; Average rejection per topic, 36. Honor men for the year: State Board, 0; Homeopathic Board, 3; Eclectic Board, 0.

Therapeutic Hints.

Flatulence.—

℞ Mag. carbonat.
Sacchar. alb. ..... āā 10.0
Bismuthi subsalicylat.
Salolis.
Fruct. cari. ..... āā 5.0
M. ft. pulv. Sig.: A teaspoonful after eating.

—Kantorowicz.

Lead and Opium Wash.—A simple and cheap method of prescribing this valuable lotion is as follows:

Tr. Opii
Liq. Plumbi Subacetat. ..... āā ℥ss

—*Wisconsin Medical Journal.*

M. Sig.: Add entire contents of bottle to one pint of water and apply locally.

Pyemia.—

℞ Syr. ferri hypophosphitis.
Liq. hydrogen peroxide. ..... 10 vol
Glycerinæ ..... āā 15.0
Aquæ ..... q.s. ad. 180.0
M. Sig.: Tablespoonful three times a day.

—Guiteras, *Medical Review of Reviews.*

Scarlet Fever.—Early in the disease Wiest begins to give the following:

℞ Tr. digitalis (fresh) ..... ℥ss
Liq. ammon. acetat. (fresh) ..... ℥iss
Spt. æther, nit. ..... ℥ii
Syr. tolu. ..... ℥ss
Aquæ cari. ..... ℥ss
M. Sig.: Teaspoonful every 3 hours.

For the itching Shollenberger uses an ointment having this composition:

℞ Menthol ..... gr. x
Ung. zinci oxidi. ..... ℥ss
Lanolini ..... q.s. ad. ℥ss
M. Sig.: Apply locally.

—*Denver Medical Times.*

Pruritus Ani.—Drueck says that when the pruritus is due to proctitis, hemorrhoids, fissure, ulceration, fistula, prolapse, or polypus, and the patient refuses to submit to surgical treatment, or in senile, debilitated, or hemorrhagic subjects, much relief may be given by the use of the following:

℞ Calomel ..... gr. 30
Menthol ..... gr. 10 to 20
Vaseline ..... ℥ i
Sign.—Apply after each bowel movement, bathing the surface carefully, and sopping it dry.

For eczema of the anus he employs:

℞ Picis liquidæ ..... ℥iv
Ung. belladonnæ ..... ℥ii
Ac. carbolici ..... ♏x
Adeps lanæ ..... ℥ii

Bathe the parts repeatedly in water as hot as can be borne, and in green soap, to remove the thickened scales, and to deplete the local circulation. In exaggerated cases, a solution of caustic potash, five grains to the ounce, may be used. A cloth may be used to sop the hot water on the parts, but do not allow any rubbing.

—*Chicago Medical Recorder.*

Chordee.—W. J. Robinson states that the following are useful prescriptions:

℞ Codeinæ phosph. ..... gr. 1-3
Heroini hydrochlor. ..... gr. 1-12
Camphoræ monobrom. ..... grs. 2
Lupulini optimi. ..... grs. 3
Ext. rhamni purshianæ. ..... grs. 2
M. Ft. caps. No. 1. Sig.: Take one capsule before retiring.

Sometimes suppositories prove the most efficient, and the following is an excellent combination:

℞ Codeinæ phosph. ..... gr. 1-2
Atropinæ sulph. ..... gr. 1-120
Antipyrinæ ..... gr. 5
Ol. theobromæ ..... gr. 15
M. Ft. suppos. No. 1. Dentur tales doses No. 12. Sig.: Insert one before going to bed; another one may be used during the night.

To relieve the actual attack, the patient should wrap a cloth or towel wrung out of ice water about the member, or put it in hot water, as hot as can be borne. If the desire to urinate is present at the same time with the chordee, the patient should urinate in the water. Swallowing pieces of ice has relieved many patients, but whether suggestion plays a part here or not is hard to determine.

GASTROSCOPY.*

By CHEVALIER JACKSON, M.D.,

PITTSBURG, PA.

LARYNGOLOGIST AND RHINOLOGIST TO THE WESTERN PENNSYLVANIA HOSPITAL, THE EYE AND EAR HOSPITAL, AND THE MONTEFIORE HOSPITAL.

When, in these days of limited fields of work, a man feels it incumbent upon him to write upon the examination of an organ to which he has not devoted a lifetime of study, some apology is necessary.

During the course of his esophageal work, from time to time, the writer has looked into the stomach. He has found that an elongated model of his esophagoscope makes a very satisfactory gastroscope. The results obtained have been so brilliant that he feels it his duty to call the attention of those interested in the stomach to the feasibility of gastroscopy. The cases herewith reported were not examined with test meals and the other aids of the gastroenterologist, as every opportunity was immediately taken advantage of to test the possibilities of gastroscopy. Delay to get complete chemical and clinical data would have resulted in missing some examinations. It is not intended to compare the results of gastroscopy with those of other diagnostic and therapeutic aids. I am utterly incompetent by lack of training and inclination to examine a stomach case in any other way than gastroscopically, and it has been my purpose only to demonstrate the feasibility of this way and to call the attention of the gastroenterologist to it. It remains for him to decide whether he needs to see the organ he is treating.

The writer's training and instincts are rhinolaryngological, so that it is natural to look upon every disease from an anatomical viewpoint, and to feel that to treat any organ without seeing it is but groping in the dark. Yet reflection enables him to realize that the internist and the gastroenterologist of to-day wish to know the perversion of physiological function, as well as the anatomical basis of disease. A simple gastroscope that can be used in practically every case where needed, is offered modestly as an addition to the armamentarium of the physician and surgeon. The views are so clear and satisfactory that the writer believes that the end of the next decade will see the internist and the gastroenterologist passing the gastroscope as frequently as the gynecologist of to-day passes the cystoscope. The gastroenterologist will not see all of the ventricular mucosa, any more than the rhinologist sees all of the nasal mucosa.

History.—When I first obtained good endoscopic views of the stomach I thought it had never been attempted before. But a search of the literature brought to light several previous attempts.

The first recorded attempt to construct a gastroscope was by Mr. Leiter and Dr. Nitze, whose names are inseparably connected with the cystoscope. Both before and after this time attempts to construct flexible and jointed instruments containing optical apparatus had failed in the mechanical stage.

Trouvé, in 1873, perfected a polyscope, with which Collin of France demonstrated endoscopically the functions of the stomach of a bull, and with which Ledentu and Raynaud diagnosticated a cicatricial stricture of the esophagus near the cardia.

Mikulicz in 1881 started on the basis that a gastroscope must be rigid, but after repeated trials he came to the conclusion that a straight, rigid instrument could not be passed into the stomach on account of the physiological curve of the vertebral column, to accommodate his instrument to which he gave the instrument an angle of 150° at the junction of the ventral and middle thirds. This angle prevented a rotation of more than 180° within the stomach, so that two complete instruments were necessary with windows opening in opposite directions. To touch the gastric walls meant to fog the window and dim the image.

Mikulicz arrived at the conclusion that a straight instrument was absolutely impracticable; that it could be passed as far as the cardia, which he believed to be located at the eighth or ninth vertebra, where it encountered an insurpassable obstruction in the subjacent vertebra. His straight experimental staff never really reached the cardia at all. What he encountered was the constriction, anatomic and spasmodic, at the hiatus diaphragmatis and the subjacent esophageal curve.

Mikulicz' examinations were mostly on healthy persons, as he thought the normal was to be studied first, and he seemed to doubt the safety of examining the stomach in serious disease of this organ. With one exception he did not record the appearance of any lesion within the stomach, and his description of the normal is very meager and unillustrated.

After 1883 no account of the use of gastroscopy appears in literature for twelve years, and the procedure was evidently abandoned by its originator.

Rosenheim, in 1896, reported experiments with a gastroscope 12 mm. in diameter, 68 cm. in length. It was made up of three concentric tubes, the inner being a terrestrial telescope of 60°, with the addition of a prism below the objective, a different prism to be substituted to inspect different areas, the optic tube being withdrawn for the purpose.

External to the optic tube is the intermediate or illuminating tube in the walls of which four canals run; two for water circulation to cool the lamp (water at 40° C. to prevent condensation on the glass surfaces being required); a third canal for conducting wires; and a fourth canal for the purpose of inflating the stomach with air.

In addition to the straight gastroscope, Rosenheim states that in some cases the spiral twist of the lower esophagus required an instrument bent at an angle of 160° at a point 7 cm. from its distal extremity. He also used a straight rigid staff of the

*Read by invitation before the New York Academy of Medicine, Section on Laryngology, January 23, 1907

size of the gastroscope to ascertain if it were possible to pass his gastroscope in the particular case, and if passable to measure the distance that the gastroscope will have to be introduced. He also used a straight sound to overcome the reflex excitability in difficult cases. This straight sound could be introduced in only about 70 per cent. of his cases. He found that various bends and curves were necessary, and in some instances he used a corkscrew-like twist, throwing the longitudinal axes of parts of the instrument above and below the bend out of the same plane. A very significant fact is that after the beak of the instrument entered the stomach the straight part followed readily. His whole trouble in introduction was that his instrument was not designed to be passed by sight. He used cocaine anesthesia, applied with an esophageal syringe.

As to results, Rosenheim states that gastroscopy is impossible in tumor of the stomach, and that it is contraindicated in ulcer.

Rewidzof in 1899 reported results with a modified Rosenheim gastroscope which he passed through a previously introduced flexible rubber tube.

None of these early workers has left us any drawing of what he saw, and the written descriptions are hopelessly meager. The procedure has been entirely abandoned. The cause for the failure and abandonment of gastroscopy may be summed up in two words: Impractical instruments.

At the door of the Nitze cystoscope must be laid the blame of the practical failure of gastroscopy up until the present day. The attempt to adapt the cystoscopic principles to the totally different conditions in the stomach resulted in the misdirection of the earnest, able, scientific efforts of Mikulicz, Rosenheim, and Rewidzof. The instruments were difficult of introduction. The optic apparatus absorbed light and yielded a feeble image, which soon disappeared altogether from soiling of the window every time it touched the mucosa. For the same reason the apparatus could not be greased for introduction. The optic apparatus, furthermore, prevented the passage of the instruments by sight, it prevented the wiping away of secretions and the probing of suspected areas, without which little or nothing can be learned. The stomach had to be empty, which it never is. All failed to recognize the mistake of trying to see a large field in a dilated stomach. The field must be traversed in the collapsed state of the stomach, fold by fold. These things are not said in criticism, for, while the work of these pioneers was of no help to me, as mine was done before I learned of their labors, yet they have rendered great aid in determining that cystoscopic methods are not adapted to gastroscopic work. This would certainly have been tried by others, and much time and thought consumed by some one. Mikulicz himself recognized the complexity of his apparatus. He said: "There remains no doubt but that the instruments, as well as the method, furnish ample room for improvement and simplification." The simplification I think has now been reached, though of course there is still ample room for improvement.

The steps in the development of gastroscopy are these:

Mikulicz determined one point, namely, that a gastroscope must be rigid, but he gave it a bend. Rosenheim went a step farther, and said it must not only be rigid, but should be straight, though he failed at times to introduce it without a bend. Now, I think, we are ready to add four more dicta:

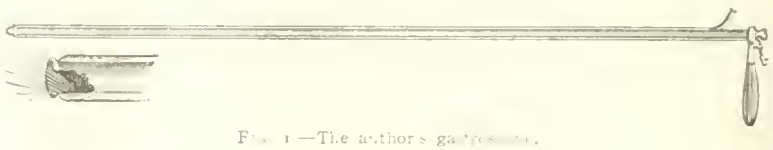

Fig. 1.—The author's gastroscope.

1. Optic apparatus must be abandoned.
2. The tube must be passed by sight.
3. The stomach must be examined in a collapsed state, to permit of mopping, palpation with the instrument, probing, and combined endoscopy and external palpation.
4. General anesthesia is indispensable to prevent retching, during which the diaphragm clamps the tube, rendering exploration impossible.

In a recent article[11, 12] I described my gastroscope

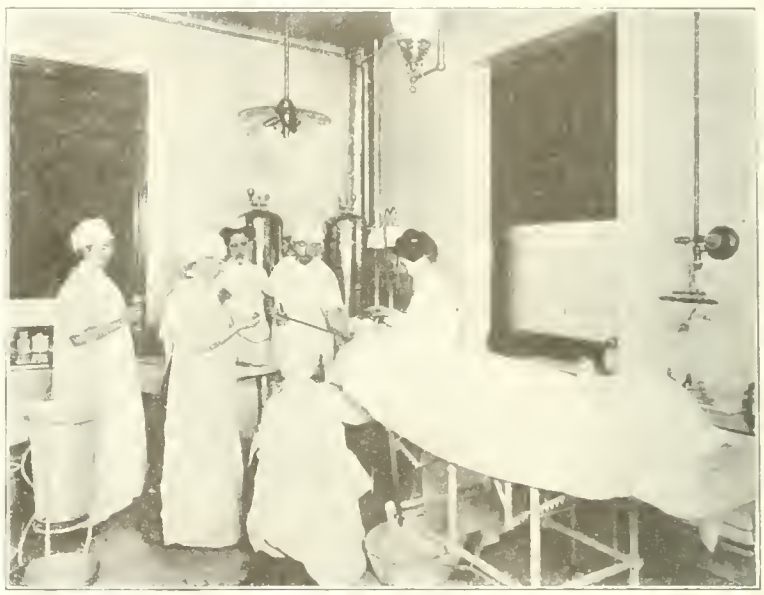

Fig. 2.—Positions of assistants, nurses, operator and patient during the introduction of the gastroscope.

and gave the technique of its use, together with a report of six cases in which I had obtained positive results from gastroscopy. I described the normal gastroscopic appearances.

The stomach is examined in the collapsed state, that is, after a twelve-hour fast. Fig. 3 gives a fair conception of one of the thousands of forms in which the stomach folds present themselves before the end of the gastroscope during the examination. There is one point upon which I did not lay sufficient stress, and that is the importance of proper gagging.

I have had more trouble in getting an assistant who can manage the gag and the patient's head than in any other part of the technique. The mouth must be gagged to the extreme limit; it must be held so, and the gag must never be allowed to slip. If it does, the tube will be damaged and its introduction interfered with.

The second assistant kneels or sits (Fig. 2) with the right arm around the patient's neck, his right hand holding the gag, which is tightened if the jaws separate wider, and his left hand controls the patient's head. He yields the head to the slightest

movement of the tube by the operator. The shoulders of the patient are at the edge of the table, and the head and neck are suspended in the air under the control of the second assistant with the gag.

The gag should always be inserted in the left side of the patient's mouth, not farther back than the canine teeth. For this I have found the Ferguson gag best, as it has sufficient spread to be used on the lateral incisors. If placed farther back, any gag is apt to slip; yet many gags have not spread enough to be used forward.

Fig. 3.—Gastroscopic view. Normal stomach. Collapsed state. Case VII.

Dangers.—In my former paper I discussed the possibility of harm from gastroscopy, but a few words may here be added on the subject. In careful hands there are no dangers other than those of ether anesthesia.

In general, it may be stated that the stomach is a very much less sensitive organ than the esophagus; not only less sensitive in the strict meaning of sensation, but in the matter of efferent impulses for the production of reflexes, and of congestion and inflammatory reactions to local irritations.

As the real question of importance is as to shock incident to the passing of a rigid instrument through the entire length of the esophagus (which, *a priori*, would seem the only question of importance, as the stomach is quite insensitive), a number of sphygmomanometric observations upon my cases were made. The following is an analysis by Dr. John W. Boyce of the charts made by himself, Dr. Helen F. Upham, and Dr. Joseph H. Barach:

"A notable fall of blood pressure has been noted in some instances of operative interferences with the esophagus, and observations have been made with some care to ascertain if there is anything analogous during the passage of the gastroscope.

Fig. 4.—Pylorus Case IX.

"The charts in the Margaret S. and Sarah McG. cases show absolutely no change that can be attributed to this manipulation of the esophagus. In the case of Henry H. a very slight (10 mm.) fall occurred while the tube was passing down the esophagus. This may have been accidental. The chart shows a slow rise to the original level while the tube was *in situ* and the inspection being made.

"In a fourth case, that of Henry A., however, the pressure fell steadily from the time the tube was inserted, and rose again when it was withdrawn, and fell a second time while the tube was in the stomach, and the mass being manipulated to bring it within the field of vision. Each time the fall aggregated 40 mm. or more, carrying the pressure down from between 120 and 130 (which seemed to be the normal for this case while under anesthesia) to below 90. Gastroscopy is apt to be done under very shallow anesthesia, and the pressure curve is particularly likely to be distorted by accidental circumstances, but in the four cases observed the readings were fairly uniform, and it seemed safe to say that there is ordinarily no appreciable disturbance of the circulation, but that in an occasional case the characteristic esophageal fall will occur from the passage of a rigid instrument of this length. In these cases, however, the pressure does not remain at the low point, but starts to rise at once, and reaches the original level while gastroscopic search is in progress."

Fig. 5.—Pylorus Case IX.

Gastroscopy certainly is not as dangerous as passing a sound or tube, for all diseased spots are seen and pressure upon them avoided. Thus, in malignant disease of the cervical esophagus, the natural constriction at the introitus is increased, and carelessness might force a stomach tube through, but with the rigid gastroscope passed by sight the growth at once is discovered. As I have stated, I start the tube with my finger, and rely upon a previous laryngoscopic examination to exclude disease of the introitus, and in two suspicious cases I found disease of the upper esophagus with the laryngeal speculum. Dysphagia with regurgitation is usual in disease of the upper esophagus; so that in dysphagia with regurgitation we may safely conclude that the disease is far enough within the esophagus to allow the tube to be started by the sense of touch without reaching the diseased tissue.

Fig. 6.—Ulcer of stomach. Case X.

Mikulicz doubted the safety of examining cases of suspected malignancy, and doubtless he was correct, with his instrument with its bend which had to be swung with necessarily imperfect control, and, most important of all, without seeing what the end was doing. With a perfectly controllable straight instrument unobscured and unweighted with a telescopic optic apparatus, the touch is gentle, certain, and under full control.

Suspicious spots can be seen and pressure upon them avoided. Disease of the abdominal esophagus, which makes a more or less sharp turn (relative to the advancing tube), would be particularly dangerous with an instrument passed blindly.

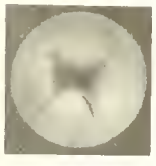

Fig. 7.—Cardiospasm. Case XI.

As to the danger of taking a specimen, I have done so in two cases without any ill result. They were both cases associated with fungation. I do not believe this to be fraught with any danger, because in the five malignant cases that I have examined there was no hemorrhage from contact of the tube or from wiping with the little gauze sponges. Yet, because a single accident might prevent or delay the adoption of what promises to be so useful a procedure, I should hesitate to remove a specimen from the edge of any flat ulceration, as there might be some risk of perforation.

The foregoing statement of dangers is based upon the utmost gentleness of manipulation under the relaxation of deep anesthesia; the passage of the gastroscope by sight; the withdrawal of it within the esophagus, should retching supervene, and upon the strict observance of all the minor details already alluded to.

I herewith report eight additional cases in which positive results have been obtained.

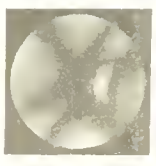

Fig. 8.—Ulcer of stomach. Case XI.

Case VII.—*Stomach lesion negatived by gastroscopy; Cardiospasm.* Miss Sarah McG., age 19, sent to me by Dr. Ewing W. Day. Patient complained of difficulty in "getting things down," often requiring a pint of water to wash down a small mor[illegible] of food. Occasional nausea an[illegible] vomiting, also regurgitation. Lost twenty pounds in weight.

Assisted by Dr. Ellen J. Patterson, with Dr. Helen F. Upham administering the ether, and with Dr. Joseph H. Barach at the sphygmomanometer, I passed the gastroscope. The patient being fully relaxed, the gastroscope slid readily down into the

stomach without resistance. The esophagus was perfectly normal. The gastric mucosa was of the most beautiful delicate pink color. Fold after fold was explored (Fig. 3) but nothing abnormal was found. Here and there a fold was drained of its fluid, which, to the naked eye, seemed normal in consistency and of a pale olive color as it ran from the tube.

Fig. 9.—Gastr. Luetic. Case XI

The tube was withdrawn to the bifurcation level, and reinserted as the patient began to come out of the anesthesia. The cardia opened and closed spasmodically.

We had here an anatomically normal esophagus and stomach, and an esophageal neurosis. The case was referred to Dr. J. A. Lichty, who reported, after tests, a functionally normal stomach. Under his skilful care the neuropathic basis was so far benefited that the symptoms entirely disappeared.

Case VIII.—*Gastric Syphilis.* Michael V., age 28, admitted to the Western Pennsylvania Hospital in the service of Dr. John W. Boyce. History of syphilis and of alcoholism. Complained of epigastric pain, worse after eating, anorexia and constipation of one or two months' duration. Vomited three times during preceding week, the vomitus containing "coffee grounds" flakes. A small mass was palpable in the epigastric region.

With the assistance of Dr. Ellen J. Patterson, Dr. J. J. Schoenig, and Dr. R. A. Brundage, I passed the gastroscope with some difficulty, owing to a defective mouth gag and an incomplete anesthesia. When the tube entered the stomach a bleeding granular mass was found somewhere near the cardia. Owing to continued bleeding and to defective aspirating and swabbing apparatus at that time at hand, I was unable to locate the mass or to get a satisfactory view of it. The mucosa seemed reddened, but even of this I could not be certain. While the bleeding was enough with my then imperfect apparatus to obscure the view, it was of no moment, the amount of blood being not over a few drams. Dr. Boyce made a diagnosis of gastric syphilis and put the patient upon specific treatment, under which he made an entire and complete recovery, the mass disappearing entirely.

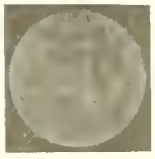

Fig. 10.—Carcinoma near pylorus. Case XIII.

Case IX.—*Gastroptosis, neurasthenia, esophagismus ("globus hystericus"); Inspection of the normal pylorus.* Margaret S., age 33, was brought by Dr. A. A. Dranga to me for esophagoscopy and gastroscopy on account of difficulty in swallowing, distress after eating. Patient was able to take food in very small morsels, finely masticated. The patient was a neurasthenic, and feared cancer, of which her mother had died.

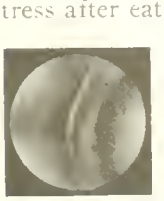

Fig. 11.—Near pylorus. Infiltration (to left). Case XIII

Dr. Dranga anesthetized the patient with chloroform, and with the assistance of Drs. Patterson, Upham, and L. L. Schwartz, with Dr. Boyce at the sphygmomanometer, I passed the gastroscope, which went into the stomach without meeting the slightest obstruction. The esophagus was absolutely normal.

The gastric mucosa was very pale, of the most delicate pink tint, and of the smoothest appearance. Considerable quantities of chloroform vapor were forced out into my eye by the respiratory movements of the stomach, so that a good deal of chloroform must have been present in the stomach, either from swallowing or by elimination, yet the gastric mucosa retained its pale tint.

The gastroscope passed on down until the distal end was 71 cm. from the upper teeth. At this distance the pylorus was reached. The pylorus was for a moment funnel-shaped, with a rounded central opening surrounded by folds parallel with the axis of the tube. The depths beyond could not be seen at first. Gradually, by a movement which was so slow, and so blended with the respiratory movement that it seemed a part thereof, the rounded opening changed to a slit (Fig. 4). This slit gradually became wider in the center, formed an oval, beyond which the duodenal folds were visible, then became surrounded by a rosette of folds at right angles to the axis of the tube. Suddenly the duodenal folds rolled in toward the tube (Fig. 5) and a small quantity of dark-looking fluid was exuded. The patient was now partially out of anesthesia and began to vomit, and the gastroscope was withdrawn within the esophagus. After deep anesthesia was again produced, and the pylorus was approached, it was found hidden behind a series of folds at right angles to the tube.

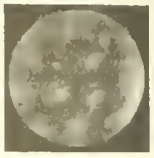

Fig. 12.—Carcinoma of pylorus Left edge of tumor.

There were now only respiratory movements, possibly because of the depth of the anesthesia. A half-hour longer, making a total of about an hour, was consumed in exploring fold after fold of the stomach. Because of the gastroptosis, this stomach could be explored over almost its entire mucosal surface.

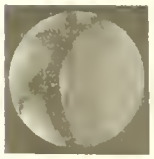

Fig. 13.—Carcinoma of pylorus. Infiltration under normal but unwrinkled mucosa. Right of picture. Case XIV.

Drs. Dranga, Patterson, Boyce, and Schwartz each examined the stomach for a few moments, and commented on the clear views obtained. After the patient began to regain consciousness the gastroscope was again introduced as far as the cardia, but was interfered with and clasped by the spasmodic contractions of the esophagus at every level.

Remarks.—This is the second case in which I succeeded in seeing the pylorus, and it was utterly unlike the first, which was seen only for a few moments, and was surrounded by annular mucosal folds. It will require, probably, hundreds of observations to determine what is the average appearance of the pylorus. The vertical position of the stomach greatly facilitated examination, which was so thoroughly made that I felt justified in assuring the patient that she had no disease of the stomach, and that the spasm of the esophagus was the cause of her symptoms. Practically all of the interior of the stomach was explored. Under Dr. Dranga's skilful care these symptoms are rapidly subsiding.

Sphygmomanometric charts of the four foregoing cases, and also of Case XIV., are analyzed under "Dangers."

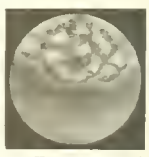

Fig. 14.—Another view of Case XIV.

Case X.—*Gastric ulcer in a patient complaining of a foreign body.* Mrs. Matirt O., age 26, sent by Dr. M. H. Moss of Homestead. Patient complained of pain on swallowing, later becoming constant, and attributed to a chicken bone swallowed four days previously. A radiograph by Dr. R. H. Boggs negatived a foreign body, but the patient insisted there was something there, pointing to the epigastrium. Gastroscopy, assisted by Drs. Clement Jones,

Ellen J. Patterson, J. M. Hamilton, and M. H. Moss, Dr. H. F. Upham giving ether. A small ulcer was found above the cardia and another on the posterior wall of the stomach (Fig. 6). The ventricular ulcer was seen by Drs. Jones, Hamilton, and Moss. An explanation of the foreign body history in this case was suggested by Dr. Clement Jones, namely, that attention was first called to the epigastric sensations by the swallowing of a very large bolus of food. Under Dr. Moss' studious care the patient is steadily improving.

Case XI.—*Peptic ulcer of the stomach and esophagus, cicatrix on gastric mucosa, ulcer of abdominal esophagus, cardiospasm, esophagismus, chronic gastritis.* Referred to me for gastroscopy by Dr. Milton I. Goldsmith. Henry H., age 59, family history and personal specific history negative, uses alcohol regularly, formerly excessively. Vomits everything he eats except raw eggs, and very small, well-chewed morsels of dry bread. Retains a small portion of milk swallowed, most of it being regurgitated. Duration six months. Symptoms attributed by patient to the drinking of large quantities of ice water. Under ether administered by Dr. Helen F. Upham, and with the assistance of Drs. Ellen J. Patterson and Milton I. Goldsmith, with Dr. Barach at the sphygmomanometer, I introduced the gastroscope. When the hiatus was passed, an ulcer directly ahead of the tube was noticed on the right wall of the esophagus. It was oval, surrounded by an inflammatory areola, though the edges were not infiltrated.

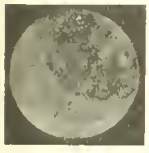

Fig. 15.— Another view of Case XIV.

In endeavoring carefully to pass the ulcer, it was noticed that as soon as the tube mouth touched the ulcer there was an immediate sudden spasmodic closure of the esophagus just below, at the cardia (Fig. 7). The patient had come partially out of anesthesia. To test the matter the tube was twice withdrawn above the ulcer and reintroduced, and each time the same cardiospasmodic phenomenon occurred. Upon pushing the ether to deep anesthesia the spasm disappeared completely and the gastroscope slid easily into the stomach. An ulcer about 1 cm. in diameter was found upon the posterior wall, to the right, in the region of the greater curvature (Fig. 8). This was plainly seen by Dr. Goldsmith and Dr. Patterson. The mucosa, deep pink in color, was covered with thick, tenacious mucus, with patches of adherent secretion that looked like an exudate in a number of locations.

Upon the greater curvature with the tube mouth pressed flatly upon the mucosa, a white, roughly quadrangular area, surrounded by a slightly pigmented (?) area of irregular outline (Fig. 9). The entire area was stiff enough to tilt and shift as one piece when moved by the tube.

Remarks.—The spot just referred to I took to be a scar. The spasmodic closure of the lower end of the esophagus, when the ulcer was touched, was, in my opinion, an esophagismus similar to sphincteric spasm in anal ulcer, though of course we do see cardiospasm and esophagismus where no ulceration exists. Again, it is possible that the ulceration may have been secondary. The ulcerations I deemed benign, because one had healed, and because they were multiple, with healthy, intervening mucosa. The gastroscope decided beyond doubt that the dysphagia and regurgitation were due to a spasmodic, not an anatomical stenosis, and that there were precancerous conditions warranting gastroenterostomy. This is a case of the kind in which the gastroscope can save the patient's life by furnishing an exact knowledge of the lesions present, thus giving the physician, or perhaps still more the surgeon, a chance to cure ere it is too late. These remarks must be qualified by the reservation that I have no knowledge of gastric medicine or surgery.

Attention should be called to the danger in this case of passing a tube blindly, and not by sight. The normal curve to the left of the abdominal esophagus presented the ulcer precisely where the point of the tube would strike it, the danger being increased by the spasm below and the absence of anesthesia. Under anesthesia, and by guiding the tube past the ulcer, with the aid of sight, rendered the procedure safe. Sphygmomanometric readings taken by Dr. Joseph H. Barach in this case are analyzed under "Dangers."

Case XII.—*Carcinoma of the cardia diagnosticated gastroscopically.* Referred by Dr. J. M. Jackson. Mrs. A. L., age 60. Family history negative. Three weeks before had noticed, for the first, pain back of sternum on swallowing, gradually increasing, and associated for two weeks with increasing difficulty in getting food down. Now only liquids can be swallowed. Some vomiting complained of, which may really have been regurgitation. It contained no blood, fresh or old. Had been under the care of a noted physician, who had cured the trouble completely, but it had recurred. Patient claimed she had lost no weight. Ether being administered by Dr. J. M. Jackson, with the assistance of Dr. Patterson and Dr. Boyce, I passed the gastroscope. The entire cardia was found filled with a fungating cauliflower-like growth, which extended up the esophagus to a point 42 cm. from the upper teeth. A slight infiltration, with narrowing, was present in the esophageal wall just above this at 38 cm., but it was not ulcerated. The fungating portion was seen plainly through the gastroscope by Drs. J. M. Jackson, Patterson, and Boyce. A large specimen was removed from near the cardia. No bleeding followed. The specimen was reported by Dr. Joseph H. Barach as squamous-celled epithelioma.

Remarks.—This case is interesting for the following points: The history of only three weeks' duration; the history of apparent cure; a large extent of disease with a history of no emaciation; the absence of signs of blood in the vomitus.

Of course, I am aware that these points would not necessarily have misled a careful diagnostician; yet they were certainly unusual. The absence of hemorrhage after the taking of so large a specimen is worthy of note.

Case XIII.—*Carcinoma of the pylorus, with ectasia, diagnosticated gastroscopically.* Gastroscopized at the request of Dr. E. S. Montgomery, who gave me the following notes of the case, from which matters irrelevant to the stomach are omitted: "Mrs. W. E. D., age 26. Complained of sharp pains through back and right side, at first intermittent, later constant. Also had deep-seated pain and tenderness one inch to the right of the median line and one and one-half inches below costal region. A small mass could be felt at this point. Family history negative."

At the Passavant Hospital, Dr. Montgomery anchored the right kidney and asked me to pass the gastroscope during the same anesthesia prior to his operation. With the assistance of Dr. Patterson, I explored gastroscopically, Dr. E. S. Montgomery looking through the tube from time to time.

The gastric mucosa was pale, of whitish pink color. Upon approaching the pylorus there suddenly came into view a dark, purplish, nodular sur-

face (Fig. 10). Beyond this mass the mucosa was of normal color, but under it hard infiltration could be felt (Fig. 11) on the left. The pyloric opening appeared somewhat triangular behind folds, one of which (Fig. 11, slightly to right of center) had a dark slit parallel with the ridge (vertical curve). Whether this was an ulcer or not I could not be certain. It was not infiltrated, and I could not turn the fold to look into the depth of the slit. Through the triangular pyloric opening poured about two ounces of cloudy, whey-like fluid, in which floated thickly, dark-brownish flakes about the size and color of coffee grounds.

The pylorus in this case was reached at 72 cm., but this was not its usual location. The whole pyloric end was quite movable, and was displaced downward into the right iliac fossa (as indicated by paralleling the tube externally with its obturator). The greater curvature was encountered when the tube reached 60 cm. The examination was not prolonged, because of the operation to follow.

Two specimens taken were reported upon negatively. Notwithstanding this, and also the age (26) of the patient, I pronounced the growth malignant on the strength of the gastroscopic findings alone.

Case XIV.—*Carcinoma of the pylorus, diagnosticated gastroscopically.* Referred to me for gastroscopy by Dr. L. S. Walton, who has given me the relevant portion of his history as follows: "Henry A., age 46; family history unknown; personal history negative; moderate drinker. Catarrhal jaundice twelve years ago; asthma for past six years." Three months ago first noticed mass in umbilical region, coincident with development of acid eructations, occasional sharp pains in upper abdomen, nausea, and vomiting. These symptoms gradually increased in severity, the vomiting occurring daily, usually about an hour after eating, the vomitus being occasionally of a brown color. Mass increased in size. Slight loss of weight and strength. Appetite remained good for meats and all his accustomed foods. Mass roughly measuring 3 inches in width by about 4 inches in height in right epigastric and umbilical regions. Percussion flatly tympanitic over mass, which is movable, and is depressed three-quarters of an inch on deep inspiration. No indications of cachexia.

At the Eye and Ear Hospital ether was given by Dr. Walton, and a gastroscopic examination was made by Dr. Clement Jones and myself. Sphygmomanometric readings by Dr. Barach. After exploring the anterior and posterior walls and greater curvature as far toward the pylorus as possible, Dr. Jones, with his right hand, grasped the stomach end of the gastroscope through the abdominal wall, while with his left hand he moved the tumor mass over in front of the tube.

Observing through the gastroscope, I saw a portion of the tumor surface of dark red color, spotted with brownish discolorations (Fig. 12). In one portion the normal, but unwrinkled mucosa, underlaid with a hard mass (Fig. 13) showed part of the tumor to be outside of the stomach wall. It seemed to occupy about two-thirds of the periphery of the pyloric third, extending over at one point to the middle third. Fig. 14 shows one point at which a zone of dilated capillaries was visible, and Fig. 15 an overhanging, dark, mulberry-like fungating nodule. There was not the slightest hemorrhage.

Owing to unavoidable circumstances, this patient was gastroscopized three hours after eating stewed chicken and drinking a glass of whiskey. A large portion of this food was in the stomach. Several pieces of the chicken tissues were removed with forceps. Some of these were as large as a peanut kernel. These were in the left third of the stomach. When the pyloric third was approached the fluid contents poured out in a steady stream, over a pint in total quantity.

What influence the posture and the anesthetic had on this distribution I do not know. This case was afterward skilfully operated upon by Dr. James McClelland, who found the location and character of the growth exactly as demonstrated by the gastroscope.

Conclusions.—1. History. The attempts made in the past to examine the stomach gastroscopically were abandoned because no practical instrument was devised.

2. *Usefulness.* Gastroscopy is not simply a feat. It has a field of usefulness that will increase as our skill and knowledge increases. Gastroscopy, in my opinion, is useful for the detection and removal of foreign bodies, the diagnosis of many pathological conditions, as inflammation, ulceration, scars, neoplasms, dilated vessels, and the treatment of at least one of these conditions, namely, benign ulcer. When the gastroscope shall have gained its deserved recognition, malignant disease of the stomach will be diagnosticated in many instances sufficiently early to give the abdominal surgeon a fair chance. Better still, a positive diagnosis of precancerous conditions will be made sufficiently early to enable him to save lives that are now being lost through reluctance of the patient to submit to an exploratory celiotomy. Gastroscopy is not offered as a substitute for an exploratory operation in every instance, but only in those cases in which the patient declines to submit, or in which the surgeon or the physician considers a simple procedure almost free from risk preferable to operative exploration.

Gastroscopy is the only method known to-day that yields ocular information as to the condition of the gastric mucosa. Other methods give information only by inference from the disturbance of function. Thus gastroscopy becomes an auxiliary.

3. *Results.*—With the gastroscope I have made a diagnosis of chronic gastritis in two cases; gastroptosis in two cases; malignant disease of the cardia in two cases, and of the pylorus in three cases; in two of these cases a specimen was taken. I have made diagnosis of peptic ulcer in five cases, one of which was cured by direct applications. In one case negative results of value were obtained. I have removed one foreign body from the stomach, being a forceps jaw lost therein by myself. In one case the gastroscopic findings enabled a diagnosis of gastric syphilis.

4. *Limitations.* Negative results from gastroscopy are of limited value, because we cannot be certain that no lesion exists in the unexplorable area. But with greater perfection and skill this unexplorable area will be very much diminished.

5. *Anesthesia* by ether is preferable. Chloroform is unsafe alone, though it may be added as needed for relaxation. Cocaine, though an adequate analgesic, does not stop the retching which will interrupt so constantly.

6. *The explorable area,* with a stomach of the classic shape and position is the middle third. More than a third of the greater curvature is readily seen, likewise of the anterior and posterior walls at their inferior portions, the lateral extent of the field diminishing upward toward the esophageal orifice. The fundus and the pyloric ends can be brought within range of the gastroscope by the external assistance of an expert abdominal manipulator, the tube being withdrawn within the esophagus until

the new field is in place. In vertical and gastroptotic stomachs, the lesser curvature and the pyloric third are readily explored with little or no external manipulation, and in some instances the pylorus can be seen.

8. *Dangers.*—In a patient with a normal esophagus and stomach, the only danger is that of ether anesthesia. An ulcer of the esophagus or stomach constitutes an exceedingly slight risk, unless the ulcer bed be so thin that it would perforate within a few days by erosion or by the normal spontaneous movements of the stomach. In chronic inflammatory states of the stomach no risks are incurred. In malignant disease a specimen may be taken with little risk in fungating conditions, but in flat ulcerations suspected of malignancy, the biting out of the edge of the ulcer, though very easy of accomplishment, is unjustifiable. The danger of hemorrhage in gastroscopy is *nil* in the normal stomach; in the diseased stomach it exists only in cases which are about to bleed, anyway, and none such were encountered in this series. There was no bleeding following the taking of a specimen in two instances.

The foregoing statement of dangers is based upon gentle manipulations, and the observance of certain rules, the most important of which is the immediate withdrawal of the gastroscope within the esophagus should retching supervene, waiting for the readvent of deep anesthesia before again pushing the tube downward.

9. Any physician can learn to examine the stomach with the gastroscope.

10. As to the future of gastroscopy: Will every physician have a gastroscope? No. No more than every physician has an ophthalmoscope.

Sterilization of Catgut.—Stich speaks highly of catgut prepared according to the following method. The catgut is wound on glass plates and is then immersed for a quarter to one-half hour in the dark in a 1 per cent. alcoholic ammoniacal solution of silver nitrate, is then washed in alcohol, and is exposed to the sunlight in a sterile container. The silver salt which has penetrated to the interior of the strand of catgut is decomposed by the light, and the material may then be preserved for use in a mixture of absolute alcohol and 10 per cent. of glycerin. Tests showed that catgut prepared in this way was perfectly sterile and was stronger then the raw material.—*Zentralblatt für Chirurgie.*

HARMFUL INVOLUTION OF THE APPENDIX.*

By ROBERT T. MORRIS, M.D.,

NEW YORK.

PROFESSOR OF SURGERY IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

My effort to catch this subject in the screw thread of professional interest two years ago did not succeed, because of the title of the published article, "Normal Involution of the Appendix." No one seems to be much interested in anything normal associated with the appendix.

Senn and Ribbert first called attention to the fact that the appendix vermiformis normally undergoes an involution process, with replacement of the lymphoid, mucous, and submucous coats by connective tissues. They attached no clinical significance to a condition which sends many thousands of patients to the doctor every year. A study of the subject brought out the fact that nerve filaments persist longer than other structures in a disappearing appendix. Contraction of the hyperplastic connective tissue irritates these nerve filaments in the appendix

FIG. 1.—Symmetrical Involution

just as it does in any sort of scar tissue elsewhere in the body. The observation pressed a button that suddenly turned on the light in a dark part of the abdomen.

Irritation of persisting nerve filaments in the involuting appendix gives us a cleanly diagnosticable class of cases that go the rounds of the profession with intestinal dyspepsia. Very often these patients go from physician to physician, without having the part of Hamlet observed in the play. In other cases the appendix takes the form of a question mark, and the patient goes from surgeon to surgeon. Like Marguerite with the petals the question runs: "He will operate; he will not operate; he will operate; he will not operate."

Whether the appendix is eventually removed or not will depend upon the personality of the last speaker in the case. Patients do not go to bed with their involuting appendices. The process is an irritative one, and is not an infective one. Further than that the involution process seems actually to guard patients against infective processes in the appendix, although these patients are quite as apt as any others to ask to have the appendix looked after. Many a surgeon has operated in these cases,

*A paper read before the meeting of the Southern Surgical and Gynecological Association, December 13, 1906.

and has removed what I termed as a normal appendix. It went into the waste basket instead of to the pathologist. The surgeon regretted that he had made a mistake in diagnosis, but the patient gained forty pounds in weight, and paid his bill. That does not satisfy a conscientious surgeon, but it sets him at thinking. The pathologist can give him an object lesson. He can show that the inner coats of the appendix are undergoing replacement

Fig. 2.—Nodular involution.

by connective tissue; that nerve filaments persist abundantly, and that the nerve filaments are surrounded by such groups of new cells that the irritation feature stands out in colors upon the map.

Normal involution of the appendix may begin in the early years of life, but most of the patients whom we see with this condition are past twenty-five years of age.

Connective tissue replacement of the appendix may, and usually does, progress evenly from the distal extremity.

Fig. 1 shows an appendix from which all normal structures, excepting peritoneum, nerve filaments, and capillaries, had disappeared. The lumen was obliterated wholly in this case. The patient had suffered from "intestinal dyspepsia" for about ten years. She was immediately cured on removal of the appendix.

Fig. 2 shows an appendix of a rather rare type, in which involution was progressing in the form of nodes. The bulging parts in the cut represent internodes of mucosa and lymphoid tissue, while the constricted parts represent nodes of connective tissue replacement of such structures. No lumen was left patent at the nodes. This patient had suffered for some years with intestinal dyspepsia, and with rather more than ordinary discomfort in the appendix region. He was cured at once by removal of the appendix.

In most of the cases we find the proximal portion of the appendix still patent and carrying a thin layer of mucosa, with involutionary changes most marked toward the distal extremity.

Fig. 3 shows a cross section of the appendix of Fig. 1. The circular line of cleavage between former tissue planes differentiates the appendix that is undergoing an involution process from the scarred appendix which is found after an infective appendicitis.

The symptoms of normal involution of the appendix begin gradually, and are usually given the dignity of the diagnostic entity of "intestinal dyspepsia." The appendix is sometimes included as a possible causative factor, but is usually left out.

What are the symptoms of normal involution of the appendix? They may be divided into two groups.

First, the group of the endless chain of symptoms running out of the hawse hole of autointoxication.

Next, four links of the chain which suffice to hold us short up to the diagnosis. These are the four links: (1) Intestinal dyspepsia; (2) a sensation of discomfort in the appendix region; (3) an appendix that feels narrow and hard on palpation; (4) hyperesthesia of the right lumbar plexus of nerves.

Now let us elaborate a bit.

(1) What are the characteristics of intestinal dyspepsia of involution appendix origin? Persistent distention of the cecum and ascending colon with gas. Irritation of the entrapped nerve filaments of the appendix irritates the intimate ganglia of the bowel wall (Auerbach's and Meissner's plexuses) and apparently causes the greatest degree of disturbance in that part of the bowel which is nearest to the original point of irritation.

(2) The sensation of discomfort in the appendix region is characteristic. The patient has a tendency to press upon the abdomen at that point with his

Fig. 3.—Transverse section of the appendix, showing replacement of the inner coats by connective tissue.

hand, or to lean against a table occasionally. The sensation may pass away for a few hours, or even for a few days at a time, but it is soon back again, and it lasts for years. Formerly I told patients that their discomfort was caused by the presence of gas in the cecum and ascending colon. I was wrong about that. Now when I hear other physicians tell patients the same thing I know that they are as wrong as I used to be.

(3) The appendix that is undergoing involution changes feels harder on palpation than a normal one. So does an Edebohls' appendix ("Congestion caused by the pressure of a loose kidney upon the superior mesenteric vein"). So also does a scar appendix. All three appendices cause symptom No. 4 (hyperesthesia of right lumbar plexus).

How are we to separate the three types of appendix?

The scar appendix goes with a history of previous infective invasion. Edebohls' appendix feels plump on palpation—the plumpness of interstitial exudation. It is often tender on pressure, and a loose right kidney is found with it.

The appendix which I describe feels narrow and hard on palpation—the hardness of hyperplastic connective tissue. It has no history of infective invasion, and there are times when it is not at all tender on pressure. Further, the scar appendix may be the seat of acute or chronic infective invasion at any time if lymphoid tissue and mucosa remain. Edebohls' appendix may be the seat of acute or chronic infection at any time, although it usually gets up protection. The appendix which I describe is not at any time the seat of acute or chronic infection, so far as I am able to learn.

(4) In the scar appendix, in Edebohls' appendix, and in the appendix which I describe, there is one constant diagnostic sign in hyperesthesia of the right lumbar nerve plexus. Press upon the abdomen at a point about one inch to the right and to the left of the navel, carrying the finger points well down toward each side of the spinal column. This will make pressure upon the right and left lumbar plexuses. The patient will tell the rest of the story.

From what other causes are we to differentiate the intestinal dyspepsia that goes with involution of the appendix?*

(*a*) From scar appendix and from Edebohls' appendix, by the features already described; (*b*) from bile-tract adhesions, "gall-spider cases," by the predominance of gastric dyspepsia, and by tenderness and muscle protection of the gall-bladder region; (*c*) from eyestrain cases, by the predominance of gastric dyspepsia in the latter, and by having the possible eyestrain factor worked out by an ophthalmologist who reports upon muscular imbalance rather than upon "the sight;" (*d*) from visceral ptoses, by the ptoses in evidence.

It is not necessary to go into further details, because bile-tract adhesions, eyestrain, visceral ptoses, and appendices undergoing involution cause such a large proportion of all dyspepsias that one who is in the habit of eliminating these causes in a diagnostic way will have his own methods for following up other dyspepsias.

What are we to say to patients who come for advice about appendices that are undergoing harmful involution? My own custom is to tell them that it is not necessary to have the appendix removed, so far as securing safety is concerned. It is merely a matter of expediency. Before I understood the subject I sometimes told patients that the appendices which were always growling might better be removed in order to avert possible explosions in the future. This advice was given upon a wrong basis. Now I tell the patients that if their physicians can keep them comfortable and maintain a good general health standard there is no need for operation—even though the operation is rather unimportant as surgical operations go. The patients leave the office relieved of their apprehensions, but a good many of them will turn up again in about a year and say that they are tired of making it a business to keep well. They have too many other things to do. They get along pretty well under medical treatment, but they weary of keeping it up. Friends get after them and persuade them to obtain a remnant lot of advice, good, bad, and indifferent.

In my first published contribution to the subject of the appendix that is undergoing normal involution changes, reasons were given for dissuading physicians from adopting the nomenclature which had been adopted by some of my assistants and by some of the physicians who for convenience' sake and for brevity had given this type of appendix my name. The nomenclature went wrong and got to stand for normal appendices. That will not do at all. I have never at any time, in speaking or in writing, advocated removal of the normal appendix, even when it appears in the field conveniently during the course of some other operation. My dictum has previously been, leave the appendix alone until it is infected and then lose no time in having it inspected.

Of late I have had to make a change, and now remove uninfected appendices that are undergoing normal involution changes, provided that the patients and their physicians are agreed upon making the request. It is a different attitude from the one that the surgeon is bound to take, on moral grounds, when a case of infective appendicitis comes under his care and responsibility.

It is a pity that the nomenclature for the appendix that is undergoing involution changes went wrong in two instances: when the title of normal involution of the appendix failed to engage professional interest, and when such an appendix called by my name got to stand for a normal appendix. Mr. Cleveland has said that in social and in political economics nothing is more dangerous than phrases. In medical economics nothing is more dangerous than nomenclature. The term "wood alcohol" has caused deaths and blindness because few people are scared by wood, and fewer still are afraid of alcohol. The term "gonorrheal rheumatism" has led to giving patients antirheumatic treatment when that sort of treatment was exactly what they could not bear. Increasing the natural physiological resistance of the patients would have been found to be the keynote to successful treatment of the cases if the word "septicemia" had appeared in place of "rheumatism." The appellation of "catarrhal appendicitis" has caused endless deaths and disaster, because it was the sand in which so many advisors hid their heads when gangrene and perforation of the appendix were impending. I have operated in very many cases of appendicitis that had been diagnosticated as "catarrhal," and have seen only one or two that could properly and safely have been classified under that title.

Let us get right on the nomenclature of normal involution of the appendix, and if it is called by any more brief term, let us not under any circumstances have it stand for the normal appendix. The subject is as important as any other subject with which the physician has to deal regularly in his daily routine of work, for there are few cases of any one sort which one will see more often than cases in which the appendix is undergoing harmful involution changes, and causing intestinal dyspepsia.

616 Madison Avenue

*Blake described, in the *Annals of Surgery* for September, 1905, similar symptoms, caused by faulty mesenteric attachment of the appendix, and some years ago I ascribed such symptoms to "torsion of the appendix." At that time the appendices had not been examined microscopically, and they may have been appendices undergoing involution changes.

THE CAUSE AND CURE OF CANCER:

AN HYPOTHESIS AND A PRACTICAL SUGGESTION BASED THEREON.

By ARTHUR C. JACOBSON, M.D.,

BROOKLYN, NEW YORK.

In the light of the hypothesis which I wish to submit, it would seem that a new line of procedure in dealing with cancer is susceptible of definition, which it is barely possible may be found to involve a measure of efficacy, if such practical application be thought worth while.

Our ignorance of the real etiology of cancer being so great, and our knowledge practically confined to studies of its ravages, one is certainly at liberty to speculate, so long as one's intellectual excursions into unknown seas are not chartless, reason and common sense minding the helm. Moreover, the disease is becoming more prevalent, challenging more and more our much boasted medical science to prove its abilty to cope with the fell scourge. In 1900 a few less than 33,000 died in the United States alone, appealing to medicine in vain. In England the death-rate from cancer is about 902 per million. In Germany, in the twenty years ending in 1898, the death-rate from cancer doubled.

Here I wish to say that some of the physiology in this paper may not seem orthodox; in fact, to some it may sound esoteric rather than scientific. But let us for once, in this matter of which we know little or nothing, follow Socrates' advice, concede our ignorance, put aside for a little while the authority of the schools, and begin all over again—divorce ourselves from mere tradition and prejudice, as Spencer did when he wrote the Synthetic Philosophy. It is not alone the scheme of spiritual salvation which may be served by thus becoming as little children—in science also this has served its purposes.

If Cohnheim could assume, hypothetically, an aberrant embryonal cell, which no one has ever demonstrated, and which, in the nature of things, is inadmissible of demonstration, then the writer feels that he can, no less properly, break new ground in the predication of principles.

Before proceeding directly to the subject proper, let us for a moment consider the present attitude of the profession toward this problem. The theory of parasitism is still somewhat to the fore, although the Harvard Commission discredits it and the Imperial Cancer Research Fund rejects all known theories and advances no new one. Those which have chiefly engrossed the attention of the profession have been Hansemann's theory of asymmetric cell division (karyokinesis); the parasitic theory of Podvyssotski and others, in which have figured the coccidium, the psorosperm, Hoffman's parasite, and the gregarina; the theory of Adamkiewicz, which affirmed that the cancer cells were themselves the parasites, merely resembling epithelial cells, and producing cancroin, which caused the cachexia; and the theory of Klebs, which alleged a fructification of epithelial cells by leucocytes. All are familiar with the theory of Beard, recently advanced.*

Here the writer would say that it is his belief that parasites may be concerned in the etiology of cancer in so far as they may constitute causes of local irritation, but he regards the feverish search of investigators for a tangible, specific cause, of parasitic nature, as futile. This subject of parasitism will be touched upon again. We shall now take up our hypothesis.

If we may conceive of the carcinomatous process as a manifestation of perverted *growth*, in other words, of perverted physiological energy (the cancer tissue, from a broad viewpoint, being not in itself histologically foreign to the organism), then may we not, without concerning ourselves too intimately with the rationale of such perversion (which in the nature of things is hardly possible of exact and scientific formulation, anyway) seek to utilize this perverted energy in vicarious channels; that is to say, divert it to sane physiological uses? We do not know what electricity is, yet we can harness it for practical purposes.

At that degenerative period of life which is so closely related to the occurrence of cancer, when cessation of the sexual functions and atrophy of the sexual organs supervene, may there not be a quota of that dynamic element that we shall call, for want of a more definitive term, physiological energy, which finds itself at a loss, as it were, for lawful occupation in the economy? What more "natural" than that, being at liberty, so to speak, it should expend its force in ways biological but mischievous. As Nature abhors a vacuum, so she abhors unused energies.

As youth is the developmental, constructive period of life, so age is the disintegrative period—disintegrative as regards the "vital forces" not less than the somatic fabric. This is a trite saying, but a truth which will bear restatement in this connection.

We are accustomed to think, and there is a basis of fact for the belief, that the races other than the white are physically inferior to the Caucasian type. The negro is certainly so, the yellow man somewhat less so. The Eskimo is a diminutive, fat, short-lived animal. The people of Burmah, Persia, Borneo, and India are certainly not characterized by surplus energy. In brief, may we not find here a partial light thrown upon the less frequent occurrence of cancer among these peoples because of a lesser sum-total of energy, which is consequently less liable to suffer mischievous diversions in some individuals at certain biological epochs, by reason perhaps of external irritations in the form of trauma, or internal influences in the form of excessive meat eating? Here even the possible presence and potential arrangement of the embryonic cell, which Senn postulates, becomes less operative, because less charged with a biological impulse both excessive and perverted and pregnant with mischievous possibilities.

Coley's occasional results in the treatment of the cancer group may depend essentially upon the cytophagous reaction which ensues after the injection of the toxins used, and which must involve the diversion and engagement of considerable energy. But the effect is ordinarily too evanescent. The setting up of an actual erysipelas when possible, or of a number of consecutive attacks of erysipelas, has been more efficacious because of the prolonged and persistent demand on the forces concerned in a very active phagocytosis and in local repair. Coley's work takes us to the very threshold of the secret and gives us a peep through the mist which veils the noumena of carcinoma and sarcoma.

Again, in the influence of oöphorectomy over mammary growths may we not find another guiding thought? May not the physiological utilization of that "body force," which operates when called upon as the inciting cause of the process of repair in a laparotomy wound and in the pelvic tissues which have been divided, account in a vicarious sense for the phenomena of retrogression in, or disappearance of, the growth?

Senger and Mohr have reported cases in which incomplete removal has been followed by cure. Linduer, Hahn, Kroenlein, Alsberg, Baer, and Steudel

*MEDICAL RECORD, February 2, 1907.

have reported cures of gastric cancer following simple gastroenterostomy. It would not seem that such results—stupendous when we consider the malignant nature of cancer—are explainable on the mere ground of removal of irritation and relief of hyperemia.

Might not analogous and perhaps curative results be obtained by the removal *from time to time* of certain epithelial structures (*e.g.* skin, as in grafting operation), as well as extirpation of the growth itself (a *sine qua non*), thus affording vicarious avenues for the operation of forces which otherwise will expend themselves in other quarters with disastrous results? The establishment of setons and issues would hardly be consonant with modern surgical principles.

From the foregoing it will be seen that our hypothesis takes account both of Cohnheim's theory and, in a sense, of parasitism. For the etiology of a benign growth we postulate Cohnheim's theory, the type of growth being determined by what type of embryonic cell is operative, plus perhaps trauma, inducing a *locus minoris resistentiæ*. Here, again, we may conceive, theoretically, of parasites furnishing the source of irritation no less than in the case of malignant growths—an incidental factor in both instances. We may also conceive of a misplaced embryonic cell as constituting *per se* a competent source of irritation, without introducing assumptions of additional factors in traumatism, due to cytolergy of some sort not necessarily related to traumatism in the conventional sense.

For the etiology of malignant growths we must postulate a further factor—perverted energy. We must also postulate a selective affinity of this perverted energy for epithelial tissues, they constituting the media for the appearance of cancer in tangible form for the reason that they are most exposed to cytolytic damage and most wanting in resistance because of their high state of differentiation.

Castration is said to have no hastening influence on the time of the occurrence of the disease. This may be due to the mutilation involved, operating in like manner to oöphorectomy.

Cancer has been known to undergo spontaneous disappearance. Here we may invoke the probable occurrence of some readjustment of the economy's energy. Some infection, say of la grippe, erysipelas, or malaria—which Dahlgetty thinks may account in some way for the relative immunity of the women of Hindoostan—may account for the phenomenon. Phagocytosis incidental to the breaking down of involved tissue may, if intense, occasionally suffice, though a local phagocytosis would not be as efficacious as a general cytophagous participation, as in erysipelas. It is essentially a question of adequate vicarious utilization of perverted energy.

Two things are commonly put forward in support of the parasitic theory of cancer. First is the tendency of cancer to form colonies or foci, and second, the tendency to lymphatic dissemination. We may regard these as simply two degrees of parasitic metastasis from the parasitic point of view, but it is possible, in the light of our hypothesis, to view them from a totally different standpoint. These metastases may be only apparently parasitic. Autoinoculations, which we have successfully produced, are essentially primary growths. So also some of these apparent metastases may really be primary in nature, just as much so as the original growth. After the original growth has led to lowered vitality and malnutrition, recognized factors in inducing that which our postulates included as a *locus minor resistentiæ*, we can see how such autoinoculations, impossible in the normal subject, become possible in the diseased. Whereas originally only one embryonic cell may have played its part in Nature's laboratory, now we are introducing many. All the postulates are satisfied and there is no need of invoking the agency of parasites. These living cells of the embryonal type, vicariously endowed with a potentiality for life and growth, are, under the special conditions, invested with powers not inferior to those of any parasite. These transposed or transplanted cells still exhibit the phenomenon of lawless growth, not because of any inherent faculty or the influence of a specific germ, but by reason of the repeated conditions already postulated. Here we must assume a surplus in the organism of perverted energy.

It is altogether likely that what we know as colonies and metastases are usually due to lymphatic dissemination, not of parasites, but of cancer cells alone. They may also be primary in some instances. It has been noted by many observers that there is a lesser tendency to metastasis in the cases occurring early in life. This is probably because all the factors are relatively less operative. Young and healthy individuals cannot be inoculated simply because the fundamental factor is wanting.

If cancer is an infectious disease, why is it that the negro, more susceptible to tuberculosis than the white man, is vastly less susceptible to cancer? The explanation lies deeper than the bacteriological domain.

Another argument against the swallowing whole of the theory of parasitism is the relative fewness of such parasites as have been found when compared to the number of cancer cells. But, of course, nobody now believes that the parasites aforesaid have any specific relation to cancer.

We have also to consider the metamorphosis of benign into malignant growths. In this case the tumor merely plays the part of a local irritation, the epochal occurrence in the organism of perverted energy furnishing the essential factor.

Here we may call attention to the fact that, after the menopause, the degenerating, atrophying female sexual organs themselves constitute, in a sense, foreign bodies, and are therefore especially liable to attack, provided a histological basis is present in the form of an errant embryonic cell of the epithelial or connective-tissue type, latent, but capable of being charged with the requisite potentiality, and awaiting only the other factors in the malignant equation.*

We know from sad experience that radical extirpation is not usually enough. Something is lacking. What this is we have attempted to analyze. Mere extirpation of the growth does not extirpate the fundamental factor. The operation exercises a salutary effect temporarily, but the cancer recurs in or near the scar when the process of repair is complete, or shortly subsequent thereto. We must in some way continue to harness the force concerned until such time as it shall cease to operate. The occasional successes of surgery depend upon the degree of potentiality of the force concerned, and, if we may so say, its "quantity." Degrees of malignancy are thereby determined.

Etiologically, cancer is of intangible, dynamic nature, which explains the baffling of investigators. They are all looking for something tangible. The tangible things they find are all secondary.

The part played by heredity is a relatively un-

*In the *Journal of the American Medical Association* of February 16, 1907 (p. 625), there is an interesting query as to the possible influence of office treatments in exciting cancerous growth. We "irritate the uterus every day or every few days for a month or a year with chemicals and foreign substances."

[illegible] probably signifies merely a transmission [illegible] resisting powers, only one factor in pathogenesis.

Cancer in the very young must also be reckoned with. About 1 per cent. of 26,574 cases collected by Bürger, De la Camp, Borst, Glaser, and Lubarsch were in persons under 30 years of age. Hofmann, Muth, Malibert, Leopold, Beigel, Eckhardt, Gurlt, Czerny, Billroth, Port, Küstner, Andouard, Brückner, Pierre, Adam, Kelly, and McBurney have reported instances in persons ranging in age from 30 down to 13 years. In 15,134 autopsies after death from cancer collected by Bürger, none of the subjects was under 15. Congenital cancer has been described, and instances have been reported in those under the age of 13, concerning which the author has no statistics immediately available. Suffice it to say that the occurrence of cancer in very early life is occasionally observed.

The maximum incidence, in all the vertebrates, coincides with the decline of reproductive activity. It is altogether likely, therefore, that its occurrence in the young is due to sexual anomalies, the nature of which we can only conjecture, but which determine maladjustments of energy.

With respect to the alleged infectiousness of cancer, we may conceive of such being possible without invalidating our hypothesis. We do not have to assume a specific parasite. It can, of course, be infectious only to those satisfying all the postulates.

Our hypotheses ought to be not merely satisfying from the scientific standpoint; they ought also to point the way to practical possibilities. "The art of healing as practised by Hippocrates and Sydenham was founded upon the nature of things and on the limits of human ability." We must to-day approach the baffling problem of cancer with our science no less than our art similarly founded upon these things.

115 Johnson Street.

OBSERVATIONS ON THE DIAGNOSTIC AND PROGNOSTIC VALUE OF THE EOSINOPHILES IN THE CIRCULATING BLOOD;

TOGETHER WITH A CASE OF RECTAL INFECTION BY SCHISTOSOMA HEMATOBIUM.

By LEONARD BLUMGART, M.D.,

NEW YORK

FORMERLY HOUSE PHYSICIAN AND HOUSE SURGEON, GERMAN HOSPITAL.

Among the various forms of leucocytes, the eosinophiles have always been regarded with a marked degree of interest, and at present are claiming more and more attention by reason of their diagnostic and prognostic worth. Rindfleisch[1] was the first to describe them as "Kornchenzellen," but it remained for Ehrlich[2] to designate them as "eosinophile Zellen." Their practical value as a means of diagnosis has been proven, especially in three groups of diseases, viz., certain diseases of the skin, the acute infectious diseases, and some of the animal parasitic affections, particularly those of the gastrointestinal tract. Neusser[3] was the first to call attention to their increase in certain skin diseases. Turk[4] pointed out their importance in the acute infectious diseases, Rieder[5] first emphasized their absence in typhoid fever, while Brown[6] and Thayer[7] were the first to observe their enormous increase in trichinosis.

The object of this paper is to direct attention to the diagnostic and prognostic worth of the eosinophiles in some parasitic and infectious diseases and to emphasize their prognostic value in typhoid fever. The cases which follow occurred in the medical division of the German Hospital, service of Dr. I. Adler.

Case I.—Male, age forty-two years, German, book agent traveling in Long Island. The family and previous history bear no relation to the present condition of the patient. Two weeks previous to admission he began to lose his appetite, feel tired, and have pain in his legs, arms, and back. This general malaise gradually increased in severity, and, feeling very ill, he left Long Island and returned to New York. The week previous to admission he had headache, vertigo, slight dyspnea, two attacks of epistaxis, and a few chilly sensations. The pains in his limbs increased in severity, so much so that walking, dressing, and, in fact, any exertion, was painful. He consulted two physicians, both of whom diagnosed typhoid fever. The night before admission to the hospital he had a slight chill, followed by fever and sweating. He had no cough. His bowels were constipated.

The physical examination showed the patient to be well developed and fairly well nourished. His mental condition was clear. The face was flushed, very slightly cyanotic, and the expression apathetic. The tongue was dry with a central coating of thick brown fur, and there was a marked tremor on protruding it. Except for the base of the left lung behind, where there was a slight dullness with harsh breathing, also a few moist râles, the lungs were normal. The pulmonic second sound was slightly accentuated; otherwise the heart was normal. The abdomen was flat and slightly rigid; there was no localized tenderness, mass, or tympanites. The skin of the abdomen showed about six maculopapular, rose-colored spots. The liver extended in the midclavicular line from the sixth rib to just below the costal margin, and its edge could be felt as smooth, round, and firm. The spleen was just palpable on deep inspiration. The extremities were held in a rigid, extended position and showed on their flexor aspects a few maculopapular spots. There was no edema of the eyelids or extremities. The axillary and inguinal glands were not enlarged. Pulse 132, temperature 104.6° F., respiration 32.

The patient was put under typhoid precautions because of the history, temperature, enlarged spleen, rose-colored spots, and general appearance. The next day a full laboratory examination was made, with the following results: Hemoglobin, 60 per cent.; red blood cells, 3,424,000; white blood cells, 15,300. Differential leucocyte count (500 cells): Polynuclears, 49.4 per cent.; lymphocytes, 5.6; large mononuclears, 5.2; eosinophiles, 39.8; basophiles, 0.0.

The examination for plasmodia was negative, also the Gruber-Widal reaction for typhoid and paratyphoid bacilli. The feces were examined for blood by the aloin test, but with negative result. No parasites were seen. The urine was acid, amber, clear; specific gravity 1022; no albumin nor sugar. The diazo reaction was positive. The differential leucocyte count of 39.8 per cent. eosinophiles in 15,300 leucocytes at once suggested trichinosis and the exclusion of typhoid fever. Careful inquiry into the patient's history now revealed the fact that five weeks before admission he had partaken of canned pork-tenderloin, which he described as being only partially smoked. The second day the patient also complained of severe pain in the deltoids, glutei, and extensors of the thigh. Sections

from these muscles showed *Trichina spiralis* in large numbers. Two days later the patient for the first time presented slight edema around the ankles; at no time was there any facial or other edema.

The patient was in the hospital for seven weeks, and during the first two weeks the temperature, general condition, and eosinophilia fluctuated synchronously. Each rise in temperature and increase of muscular pain was accompanied by a corresponding increase in the eosinophiles, which at one time reached 48½ per cent. The diazo reaction remained positive for two weeks. Repeated examinations of the blood by the Gruber-Widal test for typhoid and paratyphoid and of the feces with the Conradi-Drigalski media were negative.

No attempt was made to treat the trichinosis, except by good nursing and rectal irrigations of thymol 1-10,000, and a little stimulation with whiskey and strychnine. Recovery was very slow, the patient gaining his strength so slowly that when he left the hospital he was just able to walk without aid; on the day of discharge from the hospital he still had thirteen per cent. of eosinophiles. The patient has just recently (1906) reported his complete cure and the total disappearance of muscular symptoms.

In this case the general appearance, history, spleen, skin, and diazo reaction all suggested typhoid fever, the study of the blood alone leading to the correct diagnosis. In December, 1905, and January, 1906, there occurred in the German Hospital eight cases of trichinosis in which the diagnosis was suggested by the eosinophilia. These cases will be reported later.

Peculiar interest attaches to our next case:

Case II.—Male, thirty-seven years old, German, manufacturer, admitted December, 1904. For the past ten years the patient had lived in various parts of South America, chiefly in Brazil. Seven years ago while there he contracted typhoid fever, which kept him in the hospital for two months; one month later while recuperating in a small inland town he had an attack of acute gastroenteritis with general abdominal pain and diarrhea. He improved except for the diarrhea, which, with an occasional intermission of one to two months, had persisted up to the day of admission. The patient had five to seven defecations a day, preceded by slight colicky pains; he described the stools as being very soft, but not fluid, containing at times blood and mucus. During the last two months the diarrhea and pain had increased and he had suffered a considerable loss in weight and strength.

The physical examination showed the patient to be poorly nourished, anemic, and emaciated. The lungs and heart were normal. The abdomen was soft and there was neither mass, tympanites, nor tenderness. The liver extended in the midclavicular line from the fifth rib to four cm. below the costal margin, the edge being felt as firm, round, and smooth. The spleen was not enlarged or palpable. The colon appeared distinctly thickened and could be traced throughout its entire extent. A digital examination of the rectum showed nothing abnormal. The urine contained a trace of albumin and a moderate number of hyaline casts.

Blood Examination: Hemoglobin, 62 per cent.; red blood cells, 4,448,000; white blood cells, 5,300. Differential leucocyte count (500 cells): Polynuclears, 55 per cent.; lymphocytes, 16.2; large mononuclears, 2.8; eosinophiles, 25.0; basophiles, 1.0.

The low leucocyte count and the history, together with the absence of muscular symptoms, edema, and fever, tended to exclude trichinosis. The diarrhea which had persisted for years, the bloody character of the stools, and the increased eosinophilia all pointed strongly to a parasitic infection of some part of the intestinal tract. This was corroborated by a careful examination of the feces. The feces were a light brown, alkaline, semifluid, homogeneous mass, odor not abnormally offensive. Macroscopically there were blood-stained mucus and minute clots of pure blood. The microscope showed blood, mucus, epithelial and pus cells, triple phosphate crystals, bile pigment, and the usual enormous number of bacteria. The most important result of the examination of the feces was the discovery of two varieties of nematodes—*Strongyloides intestinalis* and *Tricocephalus trichiurus*, and one variety of trematode, *Bilharzia hæmatobia*, or *Schistosoma hæmatobium*, which were abundantly present in every stool that was examined. Adult specimens of *Strongyloides intestinalis* were not seen, neither were the eggs seen, but an abundance of rhabditiform larvæ were observed in every stool. They measured approximately 65 by 35 microns and were actively motile for hours after being passed.

Infection by the *Strongyloides intestinalis* is very common in Cochin China, where it produces the disease known as "Cochin China diarrhea." Infections have been observed in the United States. Thayer[8] reported the first three cases in 1901, and since then others[9] have described five additional cases. In the discussion following the reading of papers on the subject, physicians from the lower Southern States reported having seen a number of cases, so that it is very probable that the disease is more widespread than is generally believed.

The second variety of nematode found was the rather common *Tricocephalus trichiurus*, or *Tricocephalus dispar*. Only the eggs were seen with their characteristic bipolar, light-yellow projections.

The most interesting of this trio of parasites was the rather rare trematode *Bilharzia hæmatobia*, or *Schistosoma hæmatobium*, for the recognition of which I am indebted to Dr. Charles Wardell Stiles, Chief of the Division of Zoology of the United States Public Health and Marine Hospital Service. While investigating the diseases of Egypt, Bilharz[10] discovered the schistosoma in the urine of persons suffering from hematuria. Since then its presence has been shown to be almost universal in Africa. In the Transvaal it is so common an infection that no Boer boy is thought healthy unless he passes bloody urine (Brock[11]). Cases are being reported in increasing number from South America, and it has recently been observed in Porto Rico and the Philippines. It is also prevalent in Japan, where Tovama and Tsuchiya[12] report cases.

The infection is now considered to take place in either of two ways. Sonsino[13] claims that the infection occurs through the gastrointestinal tract by means of infected food or water, while Brock[11] considers that the mode of entrance is through the skin while bathing in infected streams. This he bases on the fact that the hundreds of cases seen by him in the Transvaal were nearly all in boys of from ten to twenty-one years, which is the bathing period of the Boer boy. The adult worm finds its way into a small vein of the portal system, becomes encysted there, and lays its eggs; these burst the wall of the vessel and so escape into the neighboring tissues and vessels. The organs most frequently involved are the bladder, ureters, pelvis of the kid-

ney, seminal vesicles, mesenteric glands, and rectum. They have been found in the liver, kidney, and prostate by Kartulis[14] and in the lungs by Mackie[15] and others, and even in the left ventricle by Greisinger.[16] The usual site of rupture is in the bladder. When the encysted worm ruptures hemorrhage occurs and when this takes place into the bladder hematuria results.

The pathological results are induration, ulceration, and polypoid vegetations. It is only in the rectum, however, that the vegetative and ulcerative changes take place. The only symptoms which seem to be constantly produced are diarrhea and pain. In our case the eggs were found in every stool examined. They were quite typical, being 0.16 mm. long and 0.06 mm. wide; the spine of the egg was placed laterally in our case, instead of terminally, which seems to be the rule in rectal infections. The cause of this difference in the location of the spine is not at present known, but the trend of thought seems to be toward the opinion that there are two different species. A proctoscopic examination revealed many small ulcers, but no polypoid vegetations were seen.

The disease is rare in the United States, only seven cases having been reported. The first case was seen by Booth[17] in 1882, the second by Curtis[18] in 1896, the third by Porter[19] in 1897. Porter's case was referred to by Brooks[20] and Sondern.[21] The fourth case was reported by Walker[22] in 1900 and again observed by the Raffertys[23] in 1904. The fifth case was seen by Pool[24] in 1903, the sixth case by O'Neil[25] in 1904, and the seventh case by Anders and Callahan[26] in 1905. Smith[27] reports seven cases occurring among Boers who came to this country for exhibition purposes after the Boer war. All these were urinary infections, while ours, I believe, is the first case of rectal infection reported in the United States.

In connection with the hypoleucocytosis, almost constantly observed in typhoid fever, is the extraordinary diminution of the eosinophiles, and in the great majority of cases their disappearance, which usually occurs in the very beginning of the infection. Reider[28] in ten consecutive cases could not find a single eosinophile in a thousand cells, while one mild infection showed 0.3 per cent. of eosinophiles. Jez,[29] Turk,[30] Zappert,[31] and others have since confirmed this observation. This is true to such an extent that in a doubtful case the diagnosis may almost be made by the presence or absence of the eosinophiles. In fact, Nägeli,[32] in view of his experience in an epidemic of typhoid fever, excludes typhoid in every case in which the characteristic absence or diminution of the eosinophiles is not demonstrable. The cause of this disappearance, according to Metchnikoff, is the inhibitory action of the typhoid toxin on the bone marrow. From all this it would seem probable that the behavior of the eosinophiles in typhoid fever would afford valuable clues as to the course of the disease. In accordance with this view 500-cell, differential leucocyte counts have been made daily in all cases of typhoid fever at the German Hospital; in all, over forty cases have been observed both in the public and private wards. Cases which retained from 0.2 per cent. of eosinophiles ran a very mild course; in the moderate and severe cases every eosinophile disappeared absolutely. In the moderate cases the eosinophiles began to reappear at the beginning of the fourth week, at first only in small numbers, from 0.2 to 0.5 per cent.; subsequently there occurs what has been called an eosinophile crisis, when they increase in number from these small percentages to from two to five per cent. within twenty-four hours. When this eosinophilia sets in and remains more or less constant, convalescence is well advanced and relapse is highly improbable. We have, however, never seen one occur under these conditions. If no eosinophilia occurs when the patient is apparently well on the way to recovery, or if having been observed the eosinophiles again disappear, it may be taken as a reliable sign that the pathological process is still active and a relapse almost certain, even though the temperature and all other conditions have apparently been normal for many days. The importance of this fact for prognosis and general management is obvious. It is our observation that until a patient has eosinophiles in his blood his condition is such that he cannot be discharged from the hospital, and we have also learned that to discharge a patient without an eosinophilia is dangerous. One patient this fall (1905) was discharged at her own request. Although her temperature and general condition had been normal for fourteen days, she had no eosinophiles; in three days she was back with a severe relapse. Another patient, who at the end of the fourth week had an eosinophile count of 2½ per cent., suddenly lost this, began to run an elevated temperature, and was afterwards proven at autopsy to have had a fresh infection resulting in a colotyphoid with tremendous hemorrhages. In all the fatal cases the lost eosinophiles were never recovered. One patient during convalescence had an eosinophilia of 3.4 per cent.; he then had a relapse, but twenty-four hours before the onset of the fever the eosinophiles disappeared. Two patients, after their temperature had been normal for two weeks, did not recover their strength, although tonics, food, fresh air, and sunshine were tried. Finally, after having been ill for nine weeks, the eosinophiles and strength returned simultaneously.

In conclusion, a few remarks based upon the foregoing observations might be made:

1. It is of importance not only to count the leucocytes, but to make a careful differential count and to repeat it frequently throughout the course of the disease, until in fact the patient is dismissed.

2. The entire disappearance or very marked diminution of the eosinophiles, together with a distinct leukopenia, goes far to establish the diagnosis of typhoid fever in doubtful cases.

3. A normal or increased percentage of eosinophiles, other things being equal, speaks against typhoid. This holds good, of course, only for the febrile course of the disease.

4. In cases of undoubted typhoid, the presence of eosinophiles, even in small numbers, during the first week is a favorable sign and speaks for a probable mild type.

5. No typhoid fever patient should be considered cured or dismissed from observation before he has regained permanently, at least, a normal percentage of eosinophiles.

For the suggestions leading to this paper and the help in preparing it I wish to thank Dr. I. Adler.

A REPORT OF FOUR LUETIC CASES UNASSOCIATED WITH OBSERVABLE SECONDARY MANIFESTATIONS.

By GEORGE M MAC KEE, M D,
NEW YORK.
INSTRUCTOR OF DERMATOLOGY AT THE UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE.

THE following histories are from cases treated in private practice, the patients having sufficient intelligence to appreciate the character of the disease in question as well as the necessity for a positive diagnosis. They aided me in every possible way in my observations, and I never had any reason to doubt their veracity.

CASE I.—Mr. A., twenty-two years of age, single, employed as a clerk in a large wholesale house. First came under observation September, 1902, presenting a small nonindurated ulcer lying in the sulcus on left side of frenum. It was impossible to estimate the incubation period because of frequent intercourse. The ulcer had been present three days and no treatment of any kind had been applied previous to the first visit. Although a diagnosis of chancroidal or herpetic ulceration was made, the possibility of syphilitic infection was explained, expectant treatment advised, and the patient placed under observation, making three visits to the office each week for a period of three months. The ulcer, which became slightly indurated, persisted for three weeks when it healed without leaving a cicatrix, although the induration remained for a week or more. He also had a mild bilateral inguinal adenitis which entirely disappeared four weeks after the ulcer healed. Six weeks after the first consultation, enlargement of the axillary and cervical glands was observed, but when the patient stated that he was subject to mild attacks of adenitis, no importance was attached to the discovery. Throughout the entire three months he remained in excellent general health, had no fever, no eruption, alopecia, throat or mouth symptoms, nor, in fact, any manifestation of secondary syphilis, and was therefore told that although the danger could possibly extend over another month he could discontinue his office visits.

On May 10, 1906, he again consulted me regarding a livid red infiltrated nonpruritic circinate patch covered with a few tenacious epidermic flakes on the palm of the left hand at the base of the thumb. The chain of glands along the radial side of the flexor surface of the forearm were the seat of gummatous degeneration, and the overlying epidermis was stained a deep copper color. The pharyngofaucial and nasal mucous membranes were extensively infiltrated. The patient also complained of severe headaches and rheumatic pains. This state of affairs had existed for about three months, the symptoms gradually increasing in severity. Six grains of the salicylate of mercury were given in divided doses by means of deep muscular injections, one grain being administered each week. As a result of this treatment the lesions promptly disappeared. Although having been advised to report again in two weeks for further treatment he has thus far failed to follow instructions. This patient absolutely denies any primary, secondary, or tertiary manifestations excepting those above mentioned. In this case one must consider the possibility of the secondary eruption occurring after the ninety-day limit and being so mild as to escape his attention in spite of the fact that he had been warned of its possible occurrence. It is also possible that primary and secondary lesions existed before or after my first series of observations, and either escaped his attention or were wrongly diagnosed. Finally he may have for some unknown reason given false answers to questions relative to his history.

CASE II.—Mr. H.,* twenty-two years of age, waiter by occupation, unmarried and presenting a history of several attacks of herpes progenitalis. On October 26, 1903, three days after sexual intercourse, he developed a group of herpetiform vesicles situated in the sulcus one-half inch from the frenum, which soon ulcerated and uniting developed a discharging ulcer about one-half inch in diameter involving the frenum and glans. Several small ulcers formed on the glans and mucous surface of the prepuce. Cleanliness was difficult in this case because of the excessive purulent discharge and a somewhat redundant foreskin. Beginning on December 23, the lesions were sparked for five minutes every second day with the current derived from the

*The history of this patient was given in an article entitled "The Treatment of Chancroidal, Herpetic, and Varicose Ulcerations by the High-Frequency Spark." Published in the *Journal of Cutaneous Diseases*, December, 1905.

secondary coil of the Piffard hyperstatic transformer, a static machine being employed as the generator. After seventeen days of such treatment the sores had entirely healed. On November 24, 1906, he presented a scaly papular syphilide on the palmar surface of the left hand, a circinate papular syphilide on the dorsal surface of both hands, and two circinate papular slightly eroded patches on the glans penis. On the left shin there was a large hypertrophied papule covered with psoriatic scales. On the outer aspect of the right foreleg there were several infiltrated patches of the papulosquamous type. These lesions had existed about six or eight weeks, but responded at once to mixed treatment. At the present writing nothing remains but the characteristic pigmentation. This patient positively declares that he never had any cutaneous lesions with which I am not acquainted, excepting an occasional attack of herpes, which were never severe enough to merit attention. He was married in the fall of 1904, and so far as can be determined his wife has never developed any signs of the disease. Inasmuch as the patient was only under personal observation for a period of seventeen days, coupled with the fact that no direct attention was given to the possibility of syphilitic infection, mild secondary manifestations could readily have been overlooked.

Case III.—Mrs. W., twenty years of age and married about one year. The first consultation was on August 8, 1904, at which time she presented a large ulcer on the right labium majora with a smaller one on the left side. Both labia were edematous and indurated. The ulcers had been present about two or three weeks. Both chains of inguinal glands were involved, but there was no adenitis elsewhere at the time, nor did any develop subsequently. A careful inspection of the entire body failed to demonstrate any other lesions of the skin or mucous membranes, excepting a very slight sore throat which only lasted three days. She was quite certain that no other eruption had existed prior to her first visit. The possible nature of the disease was explained to both the patient and her husband, who positively denied any syphilitic history, and they promised to note any suspicious symptoms. The ulcers had entirely healed by August 22, and up to September 15 not a single secondary manifestation had been observed. On this date, however, the patient gave birth to a male child of about seven and one-half or eight months' gestation. The child, which only lived a few minutes, was poorly nourished and although not having definite lesions, presented the general features of a syphilitic infant. The placenta also showed signs of degeneration. One year later another premature labor occurred at about the seventh month. This time, according to the statement of the girl's brother, the infant was covered with sores, poorly nourished and lived but a few hours. In the interval of time elapsing between the two confinements there had been no other manifestations of the disease nor had antisyphilitic treatment been administered. In September, 1906, an apparently healthy, full term child was born. The husband failed to contract the disease and they both consider my fears groundless, but it will be of no little interest to watch for future developments in this interesting family. The fact that the husband failed to become infected naturally suggests the possible source of the patient's inoculation. In this connection I recall a young woman who was married in June, 1902, and who developed a genital chancre in July of the same year, which was followed in six weeks by secondary symptoms. Her husband positively denied having had the disease, nor could I discover any manifestations of the same upon his body. Although failing to take any special prophylactic measures, he has to this time failed to contract the disease.

Case IV.—Mr. J., twenty-seven years of age, single, employed as a bookkeeper in a publishing house. This patient developed a severe attack of gonorrhea on January 17, 1903, nine days after cohabitation. Thirteen days later he developed a slightly indurated penile ulcer, which persisted for three months, leaving a cicatrix after healing. His gonorrhea, which was complicated with prostatic involvement, necessitated daily treatments for a period of four months, during which time I made daily examinations of his entire body for the secondary eruption which was certainly expected. The inguinal glands were involved, but at no time was any general adenitis, alopecia, sore throat, nor any manifestations of the suspected disease observed. Yet this patient on March 12, 1906, presented unmistakable signs of neglected syphilis. There was an ulcerating lesion of the left shin, accompanied with characteristic pigmentary changes, which had begun, according to the patient's observation, some weeks previously as a bruise, the result of an injury. The ulcer failed to improve under local applications, but promptly responded to mixed treatment. He states positively that he never had cutaneous lesions other than those recorded above.

The other histories may be defective, but surely if this patient had secondary symptoms they must indeed have been slight. Whenever a patient consults me regarding a possible primary lesion of syphilis I have always depended upon the development of the secondaries for a positive diagnosis and always supposed myself safe in so doing. I can distinctly recall many cases of young men having suspicious sores several years ago who subsequently failed to develop secondaries and who were told they need not worry longer.

In all probability the diagnosis of chancroid or ulcerated herpes in these cases was correct. For their sake at least it is to be hoped so. I specifically recall one young gentleman who contracted a sore having an incubation period of two weeks from a young woman who at the time was under treatment for secondary syphilis. This patient was placed under strict observation. The sore required several weeks to heal. At one time there appeared to be a slight macular eruption on the thorax under the arms, at the same time he became anemic and developed acne pustules upon the back. A consultation was held with an eminent syphilographer, who decided against specific infection. Under tonic treatment the patient soon regained his usual good health and has retained the same to the present writing.

Now the following question naturally arises: Upon what features can a safe diagnosis of early syphilis be made, and when should constitutional treatment be instituted? This question has been discussed in text books, in papers and at society meetings, yet the opinion of the medical profession remains divided. Fournier,[1] who is of the same opinion as Ricord,[2] starts constitutional treatment as soon as the primary lesion presents the features of the syphilitic chancre. By so doing he believes an ultimate cure is more likely to be effected. At the same time he advises extreme caution and whenever the slightest doubt exists he awaits the appearance of the secondaries. Van Buren and Keyes,[3] Lydston,[4] Wild,[5] and in fact the major-

ity of writers concur in this opinion. Dumesnil,[6] Taylor,[7] and others, on the other hand, owing to the fact that nonsyphilitic sores may simulate the typical chancre and *vice versa*, consider the difficulties of a diagnosis in this stage so great as to make the giving of mercury unjustifiable, no matter how plainly marked the case may be. The only advantage in employing constitutional treatment in the primary stage is in the possible prevention of severe secondary symptoms and to attack the disease before it becomes deeply seated. Now as a matter of fact the secondaries will appear as a rule whether mercury has been given or not. The fact that they sometimes do not occur when mercury has been given is certainly a poor criterion inasmuch as they may fail to appear in cases which have not been so treated. Regarding the effect of early treatment upon the remote course of the disease there is no good reason to believe that this method has any advantage, at any rate the evidence is as strong one way as it is the other. If energetic treatment be given immediately upon the appearance of the secondaries these symptoms will usually be very mild indeed. We must also consider the moral effect of the secondary manifestations. If during the primary period of the disease the patient receives proper instruction and is told that the diagnosis rests upon the appearance of secondary symptoms, he will naturally be impressed with the nature of the disease when these symptoms develop. On the other hand, if early treatment has been given and the secondaries fail to follow, the patient will, after a few months, unless he has unlimited confidence in his physician, doubt the diagnosis and become indifferent to the treatment. It not infrequently happens that this feeling of doubt is also shared by the physician.

A positive diagnosis can of course be made when the secondaries develop and appropriate treatment immediately begun. But when the secondaries do not follow a suspicious sore, can one without awaiting further evidence positively say that syphilis does not exist? All authors with whose writings I am familiar, although admitting that the secondary symptoms may be so mild as to be overlooked or ignored by the patient, believe they always do occur and can always be demonstrated by careful observation. It is no uncommon occurrence, especially in dispensary practice, to have patients present tertiary lesions and have no knowledge of primary or secondary symptoms. This happens most frequently in women, who often have a uterine chancre and who very often overlook the subsequent inguinal adenitis and superficial eruptions. Again the eruptions of the secondary period may be modified by being associated with other skin affections, and the true character of the disease not recognized.

The first three cases mentioned in this paper may or may not have had secondary symptoms. The fourth case did not develop them unless they appeared after one hundred and twenty days. It is of course possible that this patient may have had a neglected infection prior to my observations. Considering that the case is truly represented, it is probable that such cases are of rare occurrence, and as a rule it is safe to base a diagnosis upon the appearance or nonappearance of the secondary manifestations. It should, however, be borne in mind that these symptoms may not only be mild but entirely absent. In this connection the organism of Shaudinn and Hoffmann should receive consideration. Although the majority of investigators feel certain that this organism is the etiological factor of syphilis, there are many dissenters, and until absolute proof is forthcoming one may not be entirely exempt from criticism if the diagnosis be based upon the finding of the *Spirochæta pallida* alone. So far as I am aware, all patients having a sore in which these organisms were found have later developed secondaries, while on the other hand cases in which the pallida could not be demonstrated failed to develop secondary manifestations. I[8] reported several such cases last spring. W. B. Trimble,[9] at the ninety-seventh regular meeting of the New York Society of Dermatology and Genitourinary Diseases, reported the case of a man thirty-four years of age, presenting a lesion of the upper lip having all the features of an initial sclerosis. This patient was seen by several eminent dermatologists, who unhesitatingly made a diagnosis of chancre. A careful search for the *Spirochæta pallida* resulted negatively. This patient was under observation for four or five months, at which time the ulcer, although reduced in size, was still present, but secondary lesions had failed to develop. It is safe to state that in all probability there would be considerable difference of opinion regarding the advisability of starting mecurial treatment in this case. Dr. Trimble preferred to keep this patient under prolonged observation rather than make a positive diagnosis upon the evidence as presented. Many physicians will agree, while others will disagree with this method. I am still in accord with such procedure in spite of experience with cases as recorded in the beginning of this article. Regarding the association of the *Spirochæta pallida* with the primary and secondary lesions of syphilis, it must be remembered that they often can not be found after the process of repair sets in. They are also difficult to demonstrate upon the surface of such lesions. The search should therefore be made as early as possible and in every case it is advisable to obtain a specimen after a fairly deep curettage. In doubtful cases the chancre may be excised and microscopical sections studied. The diagnostic serum devised by Wassermann, Neisser and Bruck[10] may be employed if the necessary material is at hand.

Conclusion.—The physician must recognize and assume the responsibility of a positive diagnosis of syphilis before advising the recognized course of constitutional treatment. He may consider the features of a given case sufficient to make a diagnosis in the primary period, but the establishment of a diagnosis in this period is attended with considerable difficulty and inasmuch as the early use of mercury may modify the secondary symptoms to such an extent as to produce an hiatus in the patient's history, one certainly assumes a tremendous responsibility by this method. Although one can not absolutely depend upon the development of secondary symptoms in every case, it is undoubtedly a very rare occurrence for them to be overlooked by a physician who expects to see them appear. It would seem preferable, therefore, to accept this slight chance of ignoring a case rather than risk the possibility of condemning many, or even one innocent patient, to a life of mental misery and unnecessarily giving him several years of antisyphilitic treatment. A careful search for the *Spirochæta pallida* should be made in the primary and secondary lesions of every case, for if they are demonstrated one will add considerable strength to the diagnosis. The time is probably not far distant when a diagnosis of chancre can be based upon a diagnostic serum or by the microscopical examination of a smear preparation and the constitutional

treatment at once instituted. It is not beyond reasonable expectation to anticipate the development of an antitoxic serum, doing away with the time-honored mercury.

AN EARLY CASE OF FORMAL OPERATION FOR THE SEPARATION OF JOINED TWINS (XIPHOPAGUS).

By MAJOR CHARLES F. KIEFFER,

SURGEON UNITED STATES ARMY, FORT D. A. RUSSELL, WYOMING, ON DETACHED SERVICE WITH THE ARMY OF CUBAN PACIFICATION AT SANTIAGO DE CUBA, CUBA.

The case here reported is of great interest for two reasons. First, the illustration is an unusually good one of an extensive keloid growth. Second, the extreme interest of the history the patient gives. This patient is now in the General Hospital at Santiago de Cuba, where I saw him while making an inspection of the institution. On questioning him as to the length of time during which he suffered from keloid and the origin of the growth, the following curious history was developed. The man is very intelligent, and gives the story with abundant details. Some of these details I have been able to verify by old residents of the city. Personally I am satisfied that the history as given is substantially correct. It is well worth a place in surgical history. Venerado Rivero; negro; age 66 years. In the spring of 1840 the African village in which his mother lived was captured by slave traders and those of the unfortunate negroes who were not slain were driven to the coast as slaves over one of those routes drenched with the blood and tears of the myriad victims of this hideous traffic. He has never heard or known the name or exact location of this village further than that it was in the Congo River District. In the summer of the same year these people were herded aboard a slaver for export to America. He does not know the name of the ship, neither does he know her nationality.

While in midocean his mother fell in labor and suffered nine days without being delivered. On the eighth day of her trial the slaver (or "negrero," as he calls it) was pursued and captured by a Spanish corvette, *La Numancia*. On the following day the wretched woman's condition was discovered. The Naval surgeon on board *La Numancia* immediately performed a Cesarean section and removed a xiphopagus monster. Both were well formed males, and both were living. The mother died that same day. On the day of their birth the surgeon of the corvette separated the two children. Venerado is now living at the age of sixty-six years. His brother survived the operation three days. One of the slave women took charge of him and raised him. The party was landed in Cuba; worked for a time as contract laborers or peons, and then became free. This party is well known in Cuba as the first *emancipados*. Venerado's history was perfectly well known among them, and he has remembered all of the details as given him by his foster mother and others of the human cargo of the "negrero." They have even been able to preserve the name of the surgeon: José Brito y Boin.

The keloid began in the scar over the sternum, marking the location of the fusion with his mate. When he was eight years old, in 1848, it had grown to such proportions that an operation for its removal was made in Havana. The keloid reappeared in this location, but never grew to be very thick; but he remembers that at that time he had very small lesions at the locations of the present keloidal masses which have slowly increased with his years until they have developed into the condition as shown in the picture. He does not remember that he had any other injuries or scars at these points.

The large mass over the right temple and parietal region was removed a few years ago, but the tumor speedily grew again. The white patches under the jaw mark points of breaking down and ulceration which began about a year ago. The gross appearance at these points strongly suggests a malignant transformation of the keloid.

Certainly this case is at least as interesting as the famous and well-advertised Radica and Doodica operation, and the percentage of success was the same. Think of the different circumstances under which these operations were done! The one in a perfectly appointed amphitheatre, with the ready press to carry the news over the world. The other on the deck or in the hold of a pestilential slave ship. Remember, too, please, that in this earlier case there was no anesthesia, no asepsis or antisepsis, and that it was sixty-six years ago! I make my homage to the shade of José Brito y Boin. He was evidently a good deal of a surgeon, as well as a good deal of a man.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

New York, April 6, 1907.

THE CURABILITY OF PARANOIA.

PARANOIA has long stood as a bête noir of psychiatry. Krafft-Ebing in his fourth edition (1890) gave out as a dictum that he had never seen a patient suffering from paranoia recover. His definition, however, almost precluded the possibility of any other standpoint, and as his writings obtained a wide vogue we find the same standpoint reflected among many English and American writers, most of whom have slavishly followed Krafft-Ebing. Within the past fifteen years, however, it has been becoming evident that paranoia, in the sense in which Krafft-Ebing used the word, is not one disease, but a number, and newer investigations have thrown into high relief the fact that one is compelled to adopt Wernicke's comprehensive even if less definite term of the paranoid states, if one is to avoid the discomfort of finding one's incurable paranoiacs turn out to be curable something else. This has happened to almost all practising alienists, especially those imbued with Krafft-Ebing's ideas, although asylum physicians, who are less liable to have acute and mild paranoid conditions come before them, are less often called upon to revise their opinions.

Modern French authors—notably Anglade, in Ballet's Traité de Pathologie mentale—have attempted a comparative study of the terms used to define the paranoid states with a marked degree of satisfaction. The most marked group of these states constitutes the systematized delusional or primary paranoias, under which heading one finds the acute simple and hallucinatory forms, as well as the chronic systematized delusional ones. In the former, the prognosis, if we follow Mendel, may be cure, cure with remissions, episodic and recurrent attacks, and chronic forms. It is not certain that the recurrent cases are not referable to Kraepelin's manic depressive group, although Ziehen and his followers maintain the occurrence of a periodic paranoia with a good prognosis. As for the chronic systematized forms, the prognosis is bad. It should not be overlooked, however, that Bartels, Freyberg, Ilberg, and a number of other observers have described recoveries with fair or complete insight even in this group, and that both Wernicke and Kraepelin admit the curability of this form at times.

The old delusional manias and melancholias of our American asylums are grouped by Anglade with the secondary paranoias. These are of frequent occurrence in other psychoses following infectious diseases, and are particularly frequent in many intoxications, notably alcoholic. In this latter form delusions of jealousy, as well as persecutory delusions, are extremely common. Delusions of persecution in morphinists and cocainists are not unknown. The great group of the paranoid dements is to be classed here. The prognosis in this group is in general good, depending on the nature of the primary affection. Even the paranoid dements sometimes gain insight.

A third group of Anglade's is perhaps the most interesting from the medicolegal point of view. Here are the many half fools, half geniuses of the world—the long-haired reformers, the unsuccessful but never-daunted inventors, the erotics, and perhaps many of the perverts. Those suffering from phobias, obsessions, fixed ideas, etc., all meet in this common ground of defectives of a mild grade. Those in whom the stamp of persecutory delusions comes out with any degree of force are the subjects of the rudimentary or abortive paranoias of Morselli, Westphal, and others, or of the isolated monomanias, a term which has done so much to cloud the real nature of the defects of judgment in these individuals. In many of these the prognosis is good, especially if neurasthenic overtaxation is responsible for the efflorescence of the psychotic state.

Thus it may be seen from this short review that "die paranoische Frage," as our German friends call it, is not by any means a simple matter. With Wernicke at one side laying much emphasis on the different paranoid states, and Kraepelin on the other storing away the same patients in one or other pigeon holes of his category, until few real "paranoias" in his restricted sense remain, one has ample ground for much disputation.

THE COURSE OF LYMPHATIC INFECTIONS.

SOME years ago Weleminsky reported a series of experiments he had made on guinea-pigs in order to determine the lymphatic channels traversed by infectious agents entering the body through different portals. For this purpose he infected about 1,000 animals in different parts of the body with tubercle bacilli and then killed them at definite intervals. The result was that no matter what the site of the original infection had been, whether subcutaneous, under the chin, at the angle of the jaw, in the axilla, or in the groin, intraperitoneally, or even directly in the intestine by enema, in every case first the local lymph glands, then those lying along the route to the bronchial glands, and finally the bronchial glands themselves were invaded by the infectious process. Not until the bronchial glands had become involved did the blood stream become contaminated, that is to say, the lungs were always attacked after the bronchial glands. Weleminsky, therefore, regarded the bronchial glands as a center for the entire lymphatic system, a lymph heart, so to speak, toward which infectious streams from the periphery converge and from which infections of the blood take place.

These conclusions have recently been assailed by Beitzke on the ground that the bronchial glands might also be infected from above through inhalation or through the animal's swallowing tubercle bacilli set free through the rupture of the abscesses

formed in consequence of the subcutaneous inoculation. He also asserts that the possibility that tubercle bacilli may gain access to the bronchial glands from the blood stream has not been sufficiently considered by Weleminsky. The latter author in the *Berliner klinische Wochenschrift*, March 11, 1907, publishes a rebuttal of these criticisms, and offers further evidence confirmatory of his original standpoint. To discuss his statements in detail would require too much space, but, while there is undoubtedly much to be said on both sides, there appears to be good reason to believe that in future the bronchial glands must be accorded even greater importance in the mechanism of pulmonary infection than has hitherto been the case.

EXPERIMENTAL ARTERIOSCLEROSIS.

Hand in hand with the increasing realization of the importance clinically of the changes in blood pressure and other accompaniments of arteriosclerosis, have gone the attempts to obtain a deeper insight into the nature of the lesions of the vessel walls by endeavoring to counterfeit them experimentally. A considerable literature on the subject has already accumulated, and it seems settled that at least two substances, nicotine and adrenalin, when injected into the vessels of rabbits during considerable periods of time, in a large proportion of the cases occasion changes in the aorta which simulate the lesions of human arteriosclerosis more or less closely. Sceptics are not lacking, however, and not very long ago so good a judge of such matters as Kaiserling expressed the view that the experimenters in this field had not yet proved their point, and that an attitude of reserve in regard to their results was still advisable. He called attention especially to the fact that sufficient consideration had not been given to the condition of the blood vessels in untreated rabbits, and suggested that some one should investigate this matter in, say, a thousand animals, in order that satisfactory control statistics might be made available.

While such an attitude is perhaps unduly conservative, it is certain that some of the earlier communications on the subject were published before the results had been checked up with the necessary care. For example, Koranyi, who was one of the first to report that the adrenalin lesions could be diminished or prevented by the simultaneous injection of iodides, has recently (*Deutsche medizinische Wochenschrift*, January 31, 1907) admitted that he was mistaken in his conclusions. The iodine preparation he used has an oily base, and control experiments made by injecting oil of sesame without iodine showed that it was the oil and not the iodine that had been the effective agent. Biland even believes that the simultaneous injection of potassium iodide together with the adrenalin intensifies the damage wrought by the latter, so that the attractive supposition that an explanation had been offered of the manner in which potassium iodide exerts its beneficent action in certain cases of vascular disorder appears untenable.

Lately, Loeb and Fleischer (*Deutsche medizinische Wochenschrift*, March 7, 1907) have reported on an extensive series of experiments undertaken in order to investigate this question. They express the opinion that it is not possible by means of injections of iodine preparations to prevent the development of the adrenalin lesions in the rabbit's aorta, and state that they were not able to observe any beneficial results from the procedure. On the contrary, when large amounts of the iodides were used the effect appeared to be distinctly injurious, and the adrenalin lesions were increased in intensity instead of being diminished. Injections of small or of relatively large amounts of potassium sulphocyanate did not intensify the action of the adrenalin, and there seems a possibility that this substance may tend to prevent it. The authors consider, however, that their experiments are not conclusive as yet, and that further observations on larger series of animals are necessary before a definite statement is justifiable.

THE DIAGNOSIS OF BONE TUMORS BY AN EXAMINATION OF THE BLOOD.

Attention has been called during recent years to the peculiar picture presented by the blood in the presence of malignant metastatic deposits in the marrow of the long bones. This closely resembles a severe pernicious anemia and myelocytes are present in large numbers. The condition is believed to be due to the encroachment upon the normal boundaries of the cavity by the growth. It has been claimed that this particular blood picture, which can be definitely distinguished from an essential pernicious anemia as well as from the various leukemias, may serve as a means of diagnosis even when the original neoplasm cannot be located with certainty. The validity of this claim is apparently demonstrated in three cases reported by Schleip in the *Zeitschrift für klinische Medizin*, Vol. 59, Nos. 2 and 3, in all of which the blood changes referred to were present and at autopsy a more or less extensive infiltration of a malignant character was found to be distributed throughout the marrow of certain of the long bones.

These cases are of considerable interest from the diagnostic standpoint. In the first there was present a primary carcinoma of the stomach which gave rise to practically no symptoms, but to a number of metastatic bone deposits. The only symptom referable to the latter was a transitory pain over the tibiæ. An examination of the blood showed nucleated red cells, numerous myelocytes, and certain abnormal cell forms which were found post mortem to be identical with the cells of the metastases in the bones. In the second case the patient was the subject of a profound anemia and presented the general characteristics of Hodgkin's disease, and the suspicion of a malignant neoplasm partially confirmed by the blood picture was fully demonstrated later by the finding of a primary carcinoma of the vermiform appendix with numerous metastatic growths in the bones. In the third case the writer found certain cells which were more than half as numerous as the leucocytes. The increase in these cells was accompanied by an absolute as well as a relative decrease in the number of normal lymphocytes. These abnormal cells were at first regarded as bone-marrow cells, as initial stages of

the myelocytes, but a more careful examination showed that they were entirely different in character, and the autopsy disclosed a diffuse sarcomatous infiltration of the marrow of most of the bones together with an involvement of the lymphatic glands.

These findings are of particular interest, as a knowledge of the fact that the blood picture may afford some clue to the correct diagnosis in obscure instances of malignant disease may aid in confirming a suspicion as to the true nature of the case which could not otherwise be supported.

The Benzidin Test.

The value of Adler's benzidin test for blood has already been attested by numerous observers. Indeed, the most serious drawback that has been alleged against it is that of being too delicate, and Schumm has even expressed the opinion that owing to this excessive sensitiveness it is not suitable for ordinary use in testing feces. Schlesinger and Holst (*Münchener medizinische Wochenschrift*, March 5, 1907), however, describe a method by means of which they consider that all the advantages of the reagent are retained, and it is made available for routine use. The patient should refrain from meat for three, or better four, days and from the mixed stool of a single evacuation a portion the size of a pea is shaken up with a small quantity of water in a test tube, and the mixture boiled for a few minutes. A few drops of this fluid are added to the reagent in another test tube, and, if blood is present, a green or blue color, depending on the amount of blood, will appear. The reagent consists of a freshly prepared, saturated alcoholic solution of benzidin acidulated with glacial acetic acid. To one-half c.c. of this two to three c.c. of 3 per cent. peroxide of hydrogen solution is added. That the test performed in this way is not misleadingly delicate is shown by the fact that in a series of one hundred and fifty stools from patients supposed to have gastrointestinal ulceration or carcinoma, negative results were obtained in about one-third of the tests. The authors also recommend it highly for the purpose of detecting minimal amounts of blood in urine, and suggest the following mode of procedure. To ten c.c. of urine in a test tube one-half to one c.c. of acetic acid is added, and, after shaking, one-third of the volume of sulphuric ether is added. The whole is well shaken, and the ether extract is caused to separate completely by dropping in five or ten drops of absolute alcohol. This clear ether extract is then tested with the benzidin reagent in the manner indicated above. It was found that, performed in this way, the benzidin test was twenty times as delicate as Heller's test, and five times as delicate as the guaiac and aloin tests.

The Diagnosis of Helminthiasis.

It is often a very difficult matter to diagnose the presence of intestinal worms because they frequently lead to symptoms which are not likely to be attributed to this cause. An examination of the stools is not always reliable, for the organisms may be extruded at irregular intervals, and even frequent attempts may lead to negative results. In the belief that intestinal worms, similar to other parasitic organisms, excrete a toxin which circulates through the body of the host, it is suggested by Jefimow (*Klinisch-therapeutische Wochenschrift*, 1907, No. 2) that the diagnosis in suspected cases be aided by an examination of the urine. The test for the presence of a toxin is made by boiling a small quantity of the latter and then adding a few drops of fluid nitrate of mercury. If there are no intestinal parasites present the urine, it is claimed, becomes milky and a white precipitate is finally thrown down, otherwise it turns a gray or black color. From a large number of observations it has been found that the latter reaction is always constant when intestinal parasites are present, although there are several sources of error which must be guarded against. For two days previous to the test the patient must not be given any medicine, as there are a number of drugs which give rise to a similar urine reaction. This is particularly true of sodium bicarbonate as well as all other alkalies, of substances containing lead and sulphur, and of certain salts of iron. The salicylates, morphine, carbolic acid, zinc and copper salts, quinine, and antipyrin fail to give rise to either a gray or a black discoloration. The presence of albumin, sugar, or indican in no wise influences the test, although pus may. A positive result does not give any clue as to the variety of parasite present, although it is claimed that the reaction is much less marked with round than with flat worms. It is also stated that a microscopical examination will afford more detailed information as to the specific infection present. If a few drops of the suspected urine are evaporated on a glass slide, the finding of numerous small granular crystals is claimed by Jefimow to point to the presence of tapeworms, while a similar deposit of cruciform crystals denotes infection with the nematodes.

Pseudostenosis of the Mitral Valve.

The differentiation of the physical signs associated with organic heart disease and those of purely functional disturbances, constitutes one of the most difficult problems in cardiac pathology. A well marked presystolic murmur is often found in young individuals, and this in the presence of dyspnea on exertion and cardiac palpitation is accepted as evidence of mitral stenosis. Later examination may fail, however, to confirm this fact and the apparently well marked murmur is no longer present. In such cases we usually find symptoms of chlorosis present and the functional disturbances of the heart are of little clinical importance, their practical interest merely residing in the possibility of confusion with those produced by organic cardiac lesions. Two factors are associated in the production of these functional murmurs—the condition of the blood and the slowing of the blood stream, particularly during the presystolic phase. There may also be present some change in the manner of the auricular contractions under the influence of the increased irritability of the cardiovascular apparatus. The differential diagnosis between true mitral stenosis and the functional pseudomitral stenosis must be based entirely on the palpatory and auscultatory signs. Bard, writing in *La Semaine Médicale*, No. 30, 1906, divides the physical phenomena of mitral stenosis into two categories—those due to the passage of the blood through a narrowed ostium and those dependent upon a rigidity of the valves. The tremor on palpation and the sounds heard on auscultation may be included in the former, but neither is sufficiently characteristic of either type to permit it to be used as a basis for a differential diagnosis. A phenomenon of the second type is the short, sharp

vibration which closely follows the tremor already referred to. This sign is considered by Bard to be quite characteristic of organic mitral stenosis and is absent in the false form. In a case of pseudostenosis it is not possible moreover to determine by palpation whether this fremitus is systolic or presystolic, and it is only by auscultation that we become aware of the presystolic character of the sound, which is also much softer and weaker than the fremitus evident to the hand.

The Action of Saline Infusions in Bacterial Toxemia.

The good results attained in the treatment of toxemias of bacterial origin by the infusion of physiological salt solution has been ascribed to the excretion of the diluted toxins following an increase in heart action and blood pressure and the resultant diuresis. In other words, the process may be described as a lavage of the blood. This view of the question is contradicted, however, by Berend and Deutsch (*Centralblatt für die Grenzgebiete der Medizin und Chirurgie*, Vol. IX., No. 19), who have made a series of experiments on animals poisoned by bacterial toxins of various kinds and found that the "lavage" either with or without venesection is practically without effect, as a rapid union between the cells and the toxins always takes place which it is impossible to break up by the method mentioned. The favorable effects of saline infusions which have been a matter of clinical record must therefore be ascribed to a stimulation of the cardiac function and the increased blood pressure rather than to a diluent action, according to the observations of these writers. An exception is granted, however, in uremic conditions where the affinity between the cells and the toxins is less marked, and here the infusion combined with venesection is more truly a washing out of the system through the blood channels.

The Present Status of Ethyl Chloride as an Anesthetic.

An interesting discussion on the value of ethyl chloride was recently held before the Society of Anesthetists—as reported in the *Lancet* for March 16. Dr. Mennell stated his reasons for having practically discontinued the use of this anesthetic, his action being based upon a number of cases at St. Thomas' Hospital. He showed that ethyl chloride increased the coagulability of the blood, and that in consequence of this pulmonary embolism occurred after the use of the ethyl chloride-ether sequence more frequently than when ether was preceded by nitrous oxide. In the discussion that followed exception was taken to the alleged danger of embolism. Dr. Llewellyn Powell had seen instances of undoubted embolism, but not as yet in connection with the use of ethyl chloride. Dr. J. F. W. Silk was accustomed to employ ethyl chloride in large doses with free air dilution, the object being merely to obtain a degree of insensibility sufficient to allow for the introduction of such an anesthetic as the A. C. E. mixture. Other speakers testified to the value of ethyl chloride before ether in muscular and in alcoholic individuals. Some were unable to corroborate Dr. Mennell's conclusions as to the detrimental after-effects from ethyl chloride, and they thought that very likely some of the ill-effects described were due to the ease with which ether was used to excess in immediate sequence to ethyl chloride.

The Tuberculous Opsonic Index.

Drs. Stewart and Ritchie described at a recent meeting of the Edinburgh Medicochirurgical Society a method by which they thought tuberculosis could be discovered in the very earliest stage (*British Medical Journal*, March 16). This method consisted in the injection of a minute dose of tuberculin R, and observations of the tuberculo-opsonic index of the blood before and after inoculation. The tuberculo-opsonic index alone might give very fallacious results, as in a large number of undoubted tuberculous cases it might lie within a normal limit. When 1/500 of a milligram of tuberculin R was injected into nontuberculous subjects the opsonic index rose, but when administered to tuberculous patients it fell. If this "negative phase" appeared after inoculation of any person, the diagnosis of tuberculous disease was, in their opinion, established. Their investigations were based on a total of sixty-two cases of tuberculous disease of various forms and on thirteen nontuberculous persons.

News of the Week.

The Evil Consequences of Bossism and Oppression in Medical Organizations.—Dr. Joseph D. Bryant, now president-elect of the American Medical Association, said, in his presidential address before the Medical Society of the State of New York: "If, on our part, a spirit of fraternal oppression of any kind should develop as the outcome of organized strength, then indeed will the day of consolidation become one of mourning for the loss in fraternal fellowship and in professional station, instead, as it ought, a day of rejoicing because of the great opportunity for general good, thus brought into existence." These truths should reach a wider audience than the comparatively few who were privileged to listen to Dr. Bryant's eloquent and thought-inspiring address.

American Anti-Tuberculosis League.—This society will hold its next meeting at Atlantic City, N. J., on June 1 to 4, 1907, under the presidency of Dr. George Brown of Atlanta, Ga. The headquarters of the League will be at the Hotel Holmhurst. The chairman of the Reception Committee is Dr. Edward Guion of Atlantic City, to whom communications from those desiring further information may be addressed. The League, as announced in the notice of meeting, has been organized for the prevention of consumption: to educate the people that this is a preventable disease; to secure State aid for poor consumptives: to establish hospitals in every State in the Union. Its membership is not limited to physicians, but is open to all men of whatever calling to whom these objects appeal.

The State's Ice Supply.—Commissioner Porter of the State Board of Health, in a communication incorporated in the March issue of the bulletin of the department, states that a bill will be introduced in the Legislature designed to give the department effective powers of supervision over the business of harvesting and distributing natural ice. The Commissioner says that the department now has no authority and no funds for this purpose. The general subject of infection through ice is also discussed, and attention is called to the fact that the danger from ice that has been kept in storage for any length of time is comparatively remote. It has been found in general that bacteria are reduced in number about 50 per cent. after exposure to freezing temperatures

for a period of one hour, 90 per cent. after twenty-four hours, and practically 100 per cent. after exposure from two to three weeks. The few that are not killed after exposure for, say one month, have become so attenuated as to be unable to produce disease. On the other hand, however, Dr. Porter speaks of the real dangers of infection due to handling and distributing, to surface pollution due to the pernicious practice of flooding ice to get a thicker crop, to rains and melting snow washing pollution from side slopes on to ice already formed, and finally to the dangers of artificial ice when this has been manufactured from contaminated water and delivered to consumers before the natural process of purification has had an opportunity to become effective.

Antivivisection in This State.—A bill has been introduced in the Assembly at Albany providing for the restriction of research by means of experiments on living animals. The bill does not seek to abolish vivisection altogether, but is designed to confine experimentation of this sort to certain qualified persons. The bill provides that experiments on living animals shall be attempted only under the authority of the faculty of a college or university incorporated under New York laws or under the authority of the State Commissioner of Health, or a City Board of Health. The place where the experiment is conducted must be registered with the State Health Commissioner, who shall license the holder to pursue animal experimentation. Before and during the experiment the animal must be completely under an anesthetic. If pain is likely when the effect of the anesthetic has ceased, the animal must be killed immediately. It is further provided that the experiment must be for the advancement of knowledge useful for saving or prolonging life or alleviating suffering.

Eye-glasses for School Children.—The Board of Education is considering the advisability of providing spectacles for those of the pupils in the city's public schools who require them. According to a report made by the Committee on Elementary Schools, about 36,000 children in the schools, or about 6 per cent. of the total number, are suffering from visual defects that demand correction if the scholars are to profit to the full by the opportunities for study given them. The committee submitted four resolutions intended to cope with the problem. The first of these suggested that the Board of Estimate be requested to appropriate $30,000 for the purpose of fitting up centers for the examination of children whose sight is defective and to provide eye-glasses made to prescription. The second resolution provided that the Department of Health be requested to furnish thirty expert oculists to examine the eyes of all the pupils of the public schools who are referred to them by the medical examiners in the schools. The third authorized the Committee on Elementary Schools to invite five prominent oculists to advise the committee as to the equipment of the examination centers. The fourth authorized the Committee on Supplies to secure bids for the equipment of the examination centers and for the supply of eye-glasses, in the event of the Board of Estimate granting the appropriation asked. It is estimated that all the spectacles necessary could be purchased for about $6,000.

Spectacle Swindler.—A large number of mothers in Queens and Nassau counties have been swindled out of from $2 to $5 by a young man who impersonated a Board of Health inspector and stated that he had been sent to examine the children's eyes. He prescribed glasses, and said that these must be provided before the child could be allowed to continue at school. He then offered spectacles which he said would correct the fault, and is said to have effected a large number of sales.

Shellfish from Polluted Waters.—A report has been made by Dr. B. R. Richards of the bacteriological laboratory of the Boston Health Department showing that most of the shellfish taken from New England waters, at least, is likely to be contaminated with sewage organisms. Clams collected along the coast from Digby, N. S., to the shoulder of Cape Cod, were tested for sewage organisms, and only those dug at Yarmouth, Mass., were found to be free from infection. Oysters, most of them brought from Cape Cod, made a better showing, and in most of the samples the evidence of contamination was insignificant. Maine lobsters were found in a satisfactory state, except those that had come by land and had been packed and handled carelessly. It is stated in the report that it is a question whether shellfish taken from sewage polluted waters are safe articles of food, even if all infectious organisms have been killed by cooking.

Lectures on Public Health Topics.—The Fordham University Medical School announces a series of lectures on Tuesday afternoons in April at 4 P.M. on "Public Health Problems and Hygiene" under the auspices of the New York City Department of Health. These lectures are to be illustrated by lantern slides showing conditions and their amelioration in New York. Members of the medical profession are invited to attend. The first lecture will be given on April 9 by Dr. Thomas Darlington, Commissioner of Health of New York City, on "The City's Health." Dr. John S. Billings, Jr., Chief of the Division of Communicable Diseases, will lecture on April 16 on "The City and Tuberculosis," and on April 23 on "The City and Typhoid Fever and Other Communicable Diseases." Dr. John J. Cronin of the New York Department of Health will lecture on April 30 on "The City and School Health."

Anti-Cocaine Bill Passed.—The Assembly at Albany on March 28 unanimously passed the Smith bill, intended to restrict the use of cocaine. The bill, which was opposed by the patent medicine interests, provides that cocaine shall not be sold except on a physician's prescription, to be filled but once. Another bill has been introduced by Assemblyman Smith, which prohibits the sale and manufacture of cigarettes in this State.

New Medical Organization.—A meeting of about fifty physicians interested in insurance examinations was held in Boston last week to discuss the organization of a society composed of workers in this field. Addresses were made by Drs. E. M. Green, Charles D. Cutting, and Francis Donoghue. A committee was appointed to draft a constitution and by-laws and to nominate officers.

Tuberculous Cows in New Jersey.—It is the opinion of some of those conversant with the conditions, that in the neighborhood of 40 per cent. of the milch cows in the State of New Jersey are tuberculous. In order to encourage farmers to have their stock inspected, the State Commission on Tuberculosis in Animals is paying full value for animals killed. Recently twenty cows out of a herd of forty were found tuberculous and were condemned, the owner receiving full compensation.

Civil Service Examinations.—The State Civil Service Commission will hold examinations April 27, 1907, for the following medical posi-

tions among others. Health Officer, Town of Scio, Allegany County; Medical Superintendent, State Hospital for Tuberculosis. The last day for filing applications for these positions is April 20. Full information and application forms may be obtained by addressing the Chief Examiner of the Commission at Albany.

Society of Sanitary and Moral Prophylaxis.—A regular meeting of this Society will be held at the Academy of Medicine, Thursday, April 11, at 8:30 P.M. The following papers will be read: (1) "How and to What Effective Extent Can the Health Authorities Aid in the Prophylaxis of Venereal Diseases," by M. L. Coplin of Philadelphia; (2) "Professional Secrecy and the Obligatory Notification of Venereal Diseases," by Wm. A. Punington; (3) "The Medical Secret and the Safeguarding of Marriage from Venereal Infection," by Edward L. Keyes and Egbert H. Grandin.

For a New State Hospital.—As the State's lease of Ward's Island expires in five years, the State Lunacy Commission is making arrangements for the disposal of the 4,000 odd insane patients now quartered there. It is the plan of the commission to have the State purchase a site of large size suitable for the construction of a hospital of the colony type. It is desired to find such a site within easy access of the city, both by rail and by water. The commission has drafted a bill for passage by the Legislature at the present session to provide for a small appropriation for the expense of finding a suitable site.

Commission on Problems of Nutrition.—Under the auspices of the University of Illinois, a commission was organized at a conference held in this city last week for the purpose of conducting experiments on the effect on the consumer of the preservatives in common use in food stuffs, especially meats. The work will be done under the direction of Prof. H. S. Grindley of the department of physiological chemistry of the university, and with him on the commission are R. H. Chittenden, Professor of Physiological Chemistry of Yale; J. J. Abel, Professor of Pharmacology of Johns Hopkins University, and A. P. Mathews, Professor of Physiological Chemistry of the University of Chicago. The expense of the investigations is to be borne in part by the university and in part by some of the beef packing houses of Chicago.

Chicago Ambulance Surgeons.—Under the supervision of the Chicago Health Department, 915 calls were responded to during the first four weeks of the service by the ambulance surgeons; 577 ill and injured were removed to hospitals, 296 individuals received first aid, and of this number 99 were taken to their homes; 67 patients with contagious diseases were removed to the county and other hospitals; 40 miscellaneous cases, including 5 insane and destitute persons, were cared for, and 915 individual reports were received and filed by the Medical Inspector. Thus far the ambulance service has given excellent satisfaction.

Scarlet Fever in Chicago.—In reply to circulars of inquiry sent to physicians reporting terminated cases of scarlet fever, answers were received from nearly three hundred, reporting four hundred and ninety-nine cases, of which seventy-one were denominated atypical scarlet fever. There were also reported at the County Hospital during January thirty-seven cases of scarlet fever terminated, in February seventy-one, and in March ninety-three, making a total of seven hundred cases reported in full in answer to the circular inquiry. The ages of the patients varied from four months to fifty-seven years. The forty-four deaths occurred at the ages of one year to forty years. Four hundred and twenty-five of the cases were mild. Of the atypical cases, most of them were so described on account of the mildness of the symptoms; others because they lacked one or more of the classical symptoms. In very few cases, not over twenty reported by physicians, no peeling was observed. The County Hospital records mention that symptom in a few instances only. Four had had scarlet fever before. As to the complications, albuminuria, adenitis, otitis, and arthritis were most prominent in the order named. Eighteen cases had diphtheria at the same time, six had measles, fourteen varicella, and two pertussis. Seven had pneumonia, four endocarditis, one pericarditis, and three purulent conjunctivitis.

Automobile Rides for Hospital Patients.—Largely through the efforts of Magistrate Crane and Mr. W. E. D. Stokes, several automobile dealers and owners have made arrangements with various hospitals to send their cars once a week to take convalescent patients for an airing.

Red Cross Congress.—Miss Mabel T. Boardman and Surgeon-General O'Reilley of the Army have been designated as delegates to the International Red Cross Congress, to open in London on June 10. Four other delegates remain to be appointed by the State Department.

A New Journal.—Under the title of *The Proctologist*, the first number of a new journal to be devoted to the surgery of the rectum appears in St. Louis. It is a quarterly, and is edited and published by Dr. Rollin H. Barnes.

Rebellious Farmers.—At a meeting of about 300 farmers of Rhode Island and Massachusetts held in Swansea last week, it was decided to protest against the proposed application of the tuberculin test to the herds in the neighborhood of Fall River. This action was the result of the announcement of the Fall River Health Board, acting on a suggestion of the State Board of Health, that it would be desirable to have the dairy herds of that section properly inspected.

Infectious Disease Among Dogs.—In Chester, Pa., a large number of dogs have been discovered suffering from an infectious disease alleged to be diphtheria. To prevent its spread, all the animals attacked are being killed, and notices have been sent to all owners of dogs to report any evidences of sickness in their live stock.

A Royal Consumptive.—According to the cable despatches, King Alfonso of Spain is suffering from tuberculosis and the Spanish court is very uneasy regarding his condition.

Meningitis at Harvard.—The death of a member of the sophomore class at Harvard is reported after an illness of four days from cerebrospinal meningitis.

Williamsburg Hospital.—At the annual competitive examination for internes in the Williamsburg Hospital held last week, the first place was won by Miss Mary Crawford, a student in the Cornell University Medical School. She will be the first woman to hold such a position in a Brooklyn hospital.

Montana State Board of Health.—The new Montana State Board of Health, created under an act of the Legislature replacing the old board, at its organization meeting in Helena on March 15 elected

as *President* Dr. William J. Treacy of Helena, and *Secretary* Dr. E. D. Tuttle of Billings.

Greenwich (Conn.) Medical Society.—At the annual meeting of this organization officers were elected as follows: *President*, Dr. L. P. Jones; *Vice-President*, Dr. Frank Terry Brooks; *Secretary and Treasurer*, Dr. J. A. Clarke.

Northwest Arkansas Medical Association.—At the meeting of this society held in Ft. Smith on March 20 the following were elected as officers: *President*, Dr. W. N. Yates of Fayetteville; *Vice-President*, Dr. J. J. Smith of Van Buren; *Secretary*, Dr. J. A. Foltz of Ft. Smith; *Treasurer*, Dr. O. M. Bourland of Van Buren. Fayetteville was selected for the next annual meeting.

Western Massachusetts Homeopathic Medical Society.—The following were elected as officers at the annual meeting of this organization held in Springfield on March 20: *President*, Dr. H. C. Cheney of Palmer; *First Vice-President*, Dr. E. W. Capen of Munson; *Second Vice-President*, Dr. S. A. Lewis; *Secretary and Treasurer*, Dr. James B. Comins.

Memphis and Shelby County (Tenn.) Medical Society.—At the annual meeting of this society held in Memphis, officers were elected as follows: *President*, Dr. Alexander Erskine of Memphis; *Vice-President*, Dr. George Livermore; *Secretary*, Dr. J. W. Price, reelected.

Florida Medical Association.—The thirty-fourth annual meeting of this society will be held at Tampa, April 17, 18, and 19, 1907, under the presidency of Dr. John McDiarmid of Deland. The Secretary is Dr. J. D. Fernandez of Jacksonville.

Augusta Medical College.—In order to celebrate the seventy-fifth anniversary of this institution, arrangements are being made for a reunion of as many of its alumni as possible at the approaching commencement.

Bequests to Hospitals.—By the will of the late Dr. J. E. Lothrop of Dover, N. H., the following bequests are made, payable on the death of the testator's wife: To the Dover Children's Home, the Dover public library, and the Wentworth Hospital, $1,000 each, and to the Wentworth Home for the Aged, $500.

Dr. Reginald M. Rowls has been appointed Assistant Surgeon to the Woman's Hospital in this city.

Bequests to Hebrew Institutions.—By the will of the late Adolphus Price the sum of $500 is left to each of the following institutions: The Hebrew Benevolent and Orphan Asylum Society, the Montefiore Home for Chronic Invalids, the Hebrew Technical Institute, the Home for Aged and Infirm Hebrews, the Hebrew Sheltering Guardian Society, the United Hebrew Charities Association, the Mount Sinai Hospital, and the Children's Aid Society.

Notable Deaths.—From Holyoke, Mass., is reported the death of the oldest woman in the city, from mumps at the age of ninety-five years. A resident of Mechanicsville, Conn., said to be the heaviest man in New England, died last week at the age of forty-three years. He weighed 450 pounds, and until six months ago worked as a weaver. He died suddenly while in a Turkish bath.

Obituary Notes.—Dr. Otto Albert Weigand of Jersey City died on March 24 of tuberculosis at the age of thirty-eight years. He was graduated from Columbia University fourteen years ago.

Dr. Pemberton Dudley of Philadelphia died on March 25, at the age of seventy years, as the result of injuries received some months ago in a trolley car accident. He had been for many years dean of the Hahnemann Medical College.

Dr. George Warren Bartow of Three Bridges, N. J., died on March 28, at the age of sixty-three years. He was a member of Company A, Fifteenth Regiment, New Jersey Volunteers, and was wounded at the battle of Petersburg. At the close of the war he studied medicine, and received his degree from the College of Physicians and Surgeons in this city. He had practised in Three Bridges for thirty-four years.

Dr. Charles E. McAdams of Wichita, Kan., died suddenly of heart disease in Kansas City on March 19. He was one of the first settlers in Wichita, and had been a prominent figure in the development of the city.

Dr. E. W. Slayton of Northfield, Vt., died of cerebral hemorrhage on March 20, at the age of sixty-four years. He was born in Calais, and received his early education in Hardwick and Montpelier, receiving his medical degree from the University of Vermont. He began to practise in Albany in 1866, but two years later removed to Warren, where he spent the greater part of his life. He had occupied many official positions, and in 1898 was elected to the State Senate.

Dr. Charles R. Brown of Lynn, Mass., died suddenly of heart failure on March 21, at the age of seventy-one years. He was born in Gorham, Me., but had resided in Lynn for about thirty-five years. He was a graduate of Bowdoin College and of the Hahnemann Medical School of Philadelphia.

Dr. A. J. Willard, a former superintendent and resident physician of the Mary Fletcher Hospital, Burlington, Vt., and founder of the Mary Fletcher Hospital Training School for Nurses, is dead in his home in Swanton.

Dr. J. W. McConnell of Cornelia, Ga., died on March 20 of pneumonia, at the age of forty-four years.

Dr. Robert C. Arnett of Monticello, S. C., died on March 18 of nephritis. He was a member of the Sixth South Carolina Infantry, and was a well-known practitioner of Fairfield County.

Dr. Clement Overton Fountaine of Crystal Hill, Va., died on March 16 of heart disease at Gladys, Campbell County. He was graduated from the Medical College of Virginia in 1900. Both his father and grandfather had been well-known physicians of Buckingham County.

Dr. Albert Fox of Waterbury, Conn., died on March 20, at the age of eighty-one years. He was born in East Hartford, Conn., and had practised in Pawling, N. Y., and in Danbury, Conn. In 1900 he removed to Waterbury, where he had since resided.

Dr. Frances Van Cleve Fuller of Brooklyn died on March 27, at the age of fifty-seven years. She was born in Newark, and was graduated from the Woman's Medical College of New York in 1884. She was one of the first women to be admitted to membership in the Kings County Medical Society, and had practised in Brooklyn for over twenty years. Dr. Fuller was the treasurer of the Woman's Auxiliary of the State Militia forces in Brooklyn during the Spanish war.

Dr. Robert Farries of this city died on March 31, at the age of forty-two years. He was born in Dumfries, Scotland, but came to this country while a young man, and studied medicine at the University of Michigan and at the Long Island Medical Col-

lege, being graduated from the latter institution with the class of 1865.

Dr. LAWRENCE F. PERRY, one of the resident physicians in the Philadelphia Hospital, died of septicemia in that institution on March 28, at the age of twenty-five years. He was born in Ripon, W. Va., and was graduated from Jefferson Medical College in the class of 1905. He had served for fourteen of the eighteen months of his term.

Dr. SAMUEL CLARKE died at Philadelphia on March 28. He was graduated from Jefferson Medical College in the class of 1869.

Dr. SAMUEL D. BICKEL died at Atlantic City, N. J., on March 27. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1895.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

KALA-AZAR—CEREBELLAR TUMORS—MEMBRANOUS DYSMENORRHEA—URINE FIBROMATA—HOSPITALS—CEREBROSPINAL FEVER; THE ORGANISM—OBITUARY.

LONDON, March 15, 1907.

PROFESSOR LEONARD ROGERS devoted his third Milroy lecture to the life history of the kala-azar parasite, the mode of infection and prophylaxis. As a rule the infection is largely a house one, and on this fact he based prophylactic measures which were very successful even before the discovery of the parasite. The organism was found independently by more than one observer and the difficulties of differentiating it explains why the disease was long confounded with other chronic fevers of malarial kind. The discovery of the new parasite, the lecturer said, has done more toward clearing up Indian fevers than anything since Laveran's description of the parasites of malaria. The organism can now be found in practically every part of the body, but is more numerous in the spleen, bone-marrow, and liver. When Dr. Rogers discovered the flagellate form suggestions as to its extracorporeal stages were forthcoming. It was thought at first to be very rare in the peripheral blood, but Donovan, Christophers, and James found it in leucocytes. Others reported the parasites in the red corpuscles, but this has been questioned, it being considered that they were only on the surfaces of the red disks. It is at any rate now clear that they are present in the circulating blood in large numbers, in most advanced cases, and could enter the stomach of any bloodsucking insect which might serve as the host for future development, and this the lecturer's work has traced. The organism differs from all flagellates previously known. The cultivation must be carried on with strict attention to temperature limitations, sterility, anaërobic conditions. On considering various facts in connection with his experiments Dr. Rogers suspected that the bedbug was the carrier of the infection. In investigating these in plague patients he had previously found the contents of the stomach sterile—an unexpected result. He then tested the reaction of the fluid after sucking human blood and found it distinctly acid, showing the secretion of the organ could neutralize the alkalinity of the blood. This led him to try the effect of neutralizing or faintly acidifying his medium with a drop or two of a sterile citric acid solution, when he was rewarded with an abundant and complete development of active flagellated forms. The significance of this is obvious. The next step was to feed the bugs with infected human blood, and in this Dr. Rogers was met with fresh difficulty, the insects refusing the food in this form. He then mixed human blood from the spleen with fluid from the stomachs of the insects and succeeded in developing at suitable temperature fully flagellated forms. It then only remained to find these forms in the insects after feeding on kala-azar patients. This begun, he had to discontinue on account of his eyes, but his work was followed up by his official successor, Dr. Patton, I.M.S., who soon after wrote to him: "I have got the complete cycle of the parasite up to completely developed flagellates; there is no shadow of doubt that the bedbug transmits the disease." Something yet remains to be done to ascertain in what form the parasite is again inoculated into the human body, for the long time during which infection clings to houses suggests it may be transmitted through the progeny of the first-affected insects as in the piroplasma of dogs and cattle. Hence the lecturer said the ovaries and ovary glands should be carefully examined in fed insects for further stages of the parasite. Nevertheless, our knowledge of the organism now suffices to make the facts valuable for prophylaxis. In regard to this the lecturer described some efforts to destroy insects which had been tried with more or less success previous to the discovery of flagellates in the stomachs of bedbugs, and he concluded by emphasizing the fact that the advances he had described in our knowledge of the most terrible of all tropical diseases is a pleasing instance of increased interest in these affections leading to combined work in different places by medical men of British nationality.

In his concluding Lettsomian lecture Dr. Beevor dealt with tumors affecting the cerebellum. He said the majority of extracerebellar tumors were found in the anterior part of the posterior fossa between the cerebellum and pons close to the petrous bone. Occasionally they grew more posteriorly, compressing the lateral lobe. In both extra- and intracerebellar growths severe headache and vomiting were present. Optic neuritis was earlier in intra- than extra-tumors. Vertigo or giddiness appeared in both and the patient thought objects were revolving in the direction away from the side of his lesion. In extra-cases compression of the auditory and facial nerves was common and gave rise to symptoms. This compression did not occur in intra-cases. In the limbs paresis was associated with absent knee jerk in locomotor ataxia; in cerebellar tumor it might be combined with increase of that reflex. A healthy person executing a movement against resistance which was suddenly removed could prevent the movement being carried on by bringing into action the antagonizing muscles, but this power appeared to be lost in cerebellar tumors. Also when the patient closed his eyes the ataxy was increased, showing its origin to be central, not peripheral as in locomotor ataxia. The peculiar staggering gait was likened to a landsman trying to walk on a rolling sea, but there was a tendency to go to one side more than the other. It was difficult to say which way he would fall; he tended to deviate to the side of the lesion and so might walk in a circle; but he was conscious of this and tried to counteract it by bringing forward the shoulder of the same side. Another test was to make the patient stand on one leg and then on the other; he would be more unsteady on the same side as the lesion. That was the walk of both forms. In extracerebellar tumors the knee jerk was not altered; in intracerebellar it might be diminished on the same side, but this was very uncertain. As to the diagnosis from cerebral tumors, there was to be considered absence of mental symptoms, sphincter troubles, and epileptiform attacks. A reeling gait associated with deviation—say to the left—with weakness of movements of the eyes to the left and paresis of left limbs without alteration of reflexes, would be in favor of intracerebellar growth in the left lateral lobe. Deafness and left facial paralysis, with weakened eye and limb movements of left side, and weakness and rigidity of the right limbs with increased knee jerk and extensor plantar reflex indicated an extracerebellar tumor on the left side.

Membranous dysmenorrhea was discussed at the Gynecological Society last month. Dr. S. J. Aarons showed specimens from four cases. In none of the casts was there a cavity, though one of them showed a small opening suggestive of closure by pressure. His treatment was curettage followed by the application of nitric acid.

Dr. M. Moullin thought curettage useless and no treatment of much value. The cases he had seen were nearly all in sterile women. He had sometimes seen a second membrane passed within four days of the first, showing the rapidity with which it may be formed.

Dr. Heywood Smith could hardly imagine a dysmenorrheal membrane not to be an open sac.

Dr. Giles was interested at finding some of these casts solid, contrary to the usual teaching. As they were formed by exudation in the uterine cavity it was not very surprising that such exudation should sometimes appear solid. If the cavity was distended the exudation might solidify before the surfaces came together and so a cavity result.

Dr. Macnaughton Jones did not think treatment of these cases so hopeless as some seemed to do. He had cured some by applications of pure carbolic acid and thought curettage also did good. Arsenic internally he considered valuable.

Mr. Spanton, president, said one always had the idea the passage of these casts was part of a vicious circle.

The meeting afterwards considered the question of operations for fibroma. Dr. Dauber showed a specimen of fibroma of the ovary removed from a patient of 77. It had been fixed in the pelvis, causing complete extrusion of the uterus. He said this case proved that aged patients bore abdominal operations well. He had operated lately at ages 70 to 80 and recovery was in each case rapid and complete, as the case of the specimen shown also was.

Dr. Macnaughton Jones agreed to this and said he had a letter from a lady of 83 from whom he removed the uterus at 74.

Mr. Furneaux Jordan said a fibroid however small should always be removed if it gave rise to symptoms.

Mr. Bowreman Jessett was for operation for all fibroids. Many patients could be saved trouble and risk by early removal.

The president, Mr. Spanton, would be sorry for the society to lay down the dictum that every small fibroid should be removed.

Dr. Dauber advocated removal of every fibroid.

Dr. M. Jones protested against operations when no symptoms were produced. The greatest operators did not operate unless symptoms arose to justify them.

The fear of an epidemic of cerebrospinal fever still prevails among the public to a certain extent, but there is no sign of panic and the statements of the Medical Officers of Health are for the most part reassuring. Some of the newspapers are heedless of the effects of their statements, though for the most part they are discouraging alarm. Professor Osler has suffered an interview in which he said that both from the history of the disease and from the course of the present local outbreaks it is not likely to become a serious epidemic. It is, he added, a singularly localized disease, rarely spreading to any extent even from one city where it may be prevalent to another in the vicinity. This he illustrated by the New York outbreak of 1905-6 which was not transmitted to other cities, nor was that of Boston. So he thought an epidemic in London very unlikely, but that the Local Government Board was making a wise provision in having the disease compulsorily notified and thoroughly investigated.

Some of the papers have further published extracts from Dr. Osler's "Practice of Medicine" on the disease, with an elaborate account of the distinctions the learned professor has attained.

Prof. White has shown organisms from the Dublin cases to the Academy of Medicine. He made direct cultivations from spinal fluid obtained by lumbar puncture. From these he grew pure cultures of a diplococcus in tetrad form. He continued inoculation to the fifth generation. From animal inoculations he had only negative results. The diplococcus resembled that described by Weichselbaum, but differed in having a capsule and forming short chains. He felt sure the organism was a distinct entity. It might possibly be a modified pneumococcus. In a former outbreak he had only obtained pneumococci from a large number of cases. Prof. McWeeney also told the Academy that he had grown from fluid obtained by lumbar puncture the only organism present, a gram staining diplococcus tending to form tetrads, but which was not the same as that described by Prof. White.

On Wednesday there was an influential meeting at Lord Brassey's house in Park Lane to plead for the immediate needs of the East London Children's Hospital. It had been arranged to hold a bazaar in June, but that has been postponed because the Sunday fund collection is then made and will not give a grant to an institution appealing at the same time. Adeline, Duchess of Bedford, made an eloquent speech, contrasting the smiles of the children of the rich and those of the poor; said children's hospitals ought to be thank offerings and memorials, every cot and every object in such hospitals a gift or thank offering; they were often memorials of dead children but should oftener be thank offerings for the living. Sir William Evans-Gordon said the hospital not only provided relief and cure but instructed mothers how to take care of the children, and so tried to check infantile mortality.

The annual meeting of the Royal Sea-Bathing Hospital was held on Wednesday. The Earl of Derby (president) spoke of the splendid work it had done and pleaded for £15,000 to provide extension which was needed to meet the demands on the charity.

The death has occurred of Dr. Arthur Ernest Sansom, Consulting Physician to the London Hospital, at the age of sixty-eight. Educated at King's College, he graduated at the University of London, M.B., 1859; M.D., 1866. He was elected assistant physician to the London Hospital in May, 1874, became full physician in May, 1800, and on resigning in 1902 was made consulting physician. In 1878 he was elected a Fellow of the Royal College of Physicians. Dr. Sansom took an active part in the teaching at the London Hospital College and was much esteemed by his colleagues. He had served as examiner at the two Royal Colleges, as well as to the University of Durham and to his own University. He had also been president of the Medical Society, and among other appointments was consultant to the N. E. Children's Hospital and the Royal Hospital for Diseases of the Chest. He was the author of three works on heart diseases, including his Lettsomian lectures and of many contributions to the journals and societies on thoracic diseases, anesthetics, antiseptics, and points in clinical medicine. He contributed to *Allbutt's System* and the *Twentieth Century Practice*. He was largely instrumental in introducing the use of the sulphocarbolates.

Many of your traveled readers may remember Dr. Herbert, late Physician to the Herbert Hospital, Paris, who died on the 8th inst. He was an Oxford man where he took his M.A. and then entered as a student in Paris where he took M.D. and where he was during the siege. He was an officer of the Legion of Honor.

Dr. William Henry Pearse died on the 7th inst. at Plymouth where he had practised for over thirty years. He had previously been surgeon in the Government Emigration Service and wrote a work on "Health in Calcutta and British Emigrant Ships," 1866. He was M.D., Edin., 1851, and M.R.C.P., Edin., 1882. He contributed a number of articles on consumption and other practical papers to periodicals, chiefly to the *Medical Press* and *Circular*. All Plymouth mourns the loss of her deeply regretted and esteemed physician.

Dr. Surgeon-General J. K. Carr, M.D., retired, died on the 4th inst. in his eighty-seventh year, having been in the Medical Service of the Army from 1846 to 1875.

ACUTE PERFORATIVE PERITONITIS.

To the Editor of the Medical Record:

Sir:—In Dr. Brownson's answer, published in the Medical Record of February 16, to my criticism appearing in your issue of January 12, 1907, exception is taken to my fear that the readers of your journal might suffer by the acceptance of his misjudged conclusions, on the ground that your readers are competent to decide for themselves. I can hardly agree to that regarding all your readers unless both sides of the question are presented, and dependence on their good judgment under these circumstances is my reason for presenting the other side. Conclusions that the experienced surgeon lays down are accepted by the general practitioner for his guidance. He is the first attendant of these cases, and woe to many of them if the surgeon's assistance is called in too late by reason of said "misjudged conclusions." The doctor, in speaking of my criticism of his ideas as to the hopelessness of general peritonitis cases, first misuses quotation marks and submits an argument that at first sight seems to have some relation to the subject, but on second look proves to be entirely irrelevant. The point under consideration was operation in general peritonitis, the argument against it applies to appendicitis and not to general peritonitis. Everyone so long in practice knows what the mortality was six or eight years ago in operations for peritonitis and how loth surgeons were then to operate in this condition.

Another point, and an important one, that I spoke of in my letter was that "perforation and peritoneal infection with a temperature of 105° or 106° and pulse of 140 or 160 is a rare combination and does not represent the condition in the really bad cases." This the doctor answers by a second abuse of quotation marks, this time by omitting them, and making words that I quoted from him, and so indicated by the proper marks, look as if they were my own.

There is no practical distinction, so far as conditions indicative of operation are concerned, between peritonitis caused by the bursting of an abscess, which Dr. Brownson lays so much stress on as being the class of cases he refers to, and perforation of the appendix in the absence of surrounding protective adhesions. The fact that so much stress is laid on this particular cause, "the bursting of an abscess," suggests that one of the reasons the doctor encounters this condition so frequently may be due to what he terms "the more modern scientific treatment of to-day," which he advocates and supposedly follows in usual acute appendicitis cases. He does not operate during the "intermediary period when there is fever and distention of the abdomen." This would correspond to the period when most of the acute and really urgent cases come under the surgeon's observation. Delay in operation under these circumstances would permit the development of the usual proportion of abscesses and so supply abundant material where it is possible for the "bursting of an abscess" to occur.

The doctor wants to know why, if I advocate operation in general peritonitis because nothing is lost thereby, I do not on this principle operate on all cases of tuberculosis of the lungs, etc. He omits to remark that I gave the reason and that I distinctly stated that "the fact is that to-day a fair proportion of these patients are saved by operating on them." I have no sympathy with those who blind themselves to their duty behind the cloak of "every failure tends to discourage surgery and discourage those who

could not [illegible] with safety and benefit." I cannot see the justification for refusal of his chance of life, be it ever so small, to any individual because someone else might [illegible] operation on that account. That I am not alone in this stand I was pleased to see on reading Dr. Douglas' article on this subject in the MEDICAL RECORD of February 23, 1907, p. 304, where, among other remarks directly to the point, he says: "Suffice it to say that in private work his (the surgeon's) highest obligation is to his individual patient, regardless of how it may react either upon him, you, or the community." That strikes me as sensible.

One more statement made by Dr. Brownson I want to correct. He says "the technique of removal of the appendix adds to the risk of the operation and is of no practical benefit, since the process that forms the abscess removes the portion of the appendix that is diseased." That the remains of a gangrenous appendix may be removed by natural means is a possibility, as pointed out and explained in a previous article by me (*New York State Journal of Medicine*, August, 1906), but such disposition is decidedly exceptional. If not removed the appendix remains to cause recurrence of trouble in the future. This must be evident to anyone doing extensive work in this line and familiar with conditions encountered, and my personal experience with the few cases where I failed to remove the appendix, as well as with some cases of others where the appendix was not removed, bears out the conclusion. To give instances would take too much space here, but they are at the disposal of anyone who may ask for them.

Dr. Brownson quotes from "a well known and experienced surgeon," and from "one of the greatest authorities on appendicitis," but does not give their names that we might judge of the value of their sayings. The last quotation is very apt, and in its ambiguity could be applied to any side of any question. "It is only a question of time when all will be forced to accept this theory, as facts will overcome prejudice and tradition."

A. E. ISAACS, M.D.

240 EAST BROADWAY, NEW YORK.

Progress of Medical Science.

New York Medical Journal, March 23, 1907.

Aural Affections in Relation to Mental Disturbances.—W. S. Bryant divides aural affections with reference to mental disturbances into the following classes: (1) Cases of aural derangement which bear no relationship whatever to mental disturbances; (2) cases of aural disease causing mental irritation and leading to psychical affections, usually colored by the ear symptoms; (3) disturbances of the ear which act as causes of general exhaustion and hasten the psychic symptoms; (4) diseases of the ear which progress to loss of hearing, destroying the connection with the outside world, and thus upsetting the mental equilibrium; (5) hallucinations of hearing, which are a result of the combination of an ear affection with a psychopathic condition and which are caused by the subjective sensation of a disturbed organ of hearing falling upon deranged higher centers; and (6) affections of the ear which are secondary to the mental disturbance. He discusses these various classes and arrives at the following conclusions: (1) Insanity is usually accompanied by aural disease. In the majority of the insane the two affections are naturally dependent. (2) Hallucinations of hearing arise from tinnitus through the misinterpretation of aural stimuli under psychopathic conditions. (3) Cessation of the tinnitus can be expected to relieve the auditory hallucinations.

Pasteurization; Advantages and Disadvantages to the Consumer.—R. G. Freeman points out the distinction between efficient pasteurization and the ordinary commercial process. The home process, in which the milk, after sealing in nursing bottles, is kept at 168° F. for half an hour and then rapidly cooled, the bottles being kept sealed and used for only a twenty-four hours' supply, he strongly commends. Such milk is much safer than our cleanest raw milk. Concerning milk depot pasteurization, he notes the varying conditions in different localities, and thinks that success is more likely to follow the distribution in New York City of modified milk efficiently pasteurized in milking bottles by the supplying milk depots than by a similar distribution of raw milk. He condemns commercial pasteurization as interfering with the crusade for clean milk by making dirty milk more marketable. It gives the public a false sense of security, the public buys it, supposing it a fairly sterile milk, freed from pathogenic bacteria, while the milk in question is a highly contaminated product, which continues to deteriorate much faster than raw milk, even if kept moderately cold. The author summarizes his views as follows: There are two distinct processes known as pasteurization. (1) Efficient pasteurization in nursing bottles intended to protect the consumer of the milk from bacteria and producing a food with few bacteria, and no living pathogenic bacteria we fear in milk. (2) Commercial pasteurization intended to make marketable dirty milk which could not otherwise be kept sweet until consumed, but which usually contains, on reaching the consumer, a large number of living bacteria, including possibly pathogenic bacteria and the tubercle bacillus if it is present in the milk. Efficient pasteurization has been most valuable as used in homes and milk depots. Commercial pasteurization should be tolerated only as a temporary means of modifying the dangers of dirty milk.

The Use of Ammonia in Counteracting the Fumes of Formaldehyde.—E. V. Wilcox found that commercial formaldehyde mixed with aqua ammoniæ undergoes a rather rapid reaction, causing the development of heat and the formation of a crystalline body appearing on evaporation. This body is hexamethylenamine $(CH_2)_6N_4$, which is practically odorless. Further experiments showed that the fumes of formaldehyde could be completely neutralized by ammonia fumes and vice versa. The experiment was repeated on a large scale under the ordinary conditions of disinfecting a room. Formaldehyde was employed, and as soon as the room had been sufficiently aired to allow men to work in it, ammonia was sprinkled around and the room closed again. The odor of the original disinfectant was destroyed in half an hour. In the experiment made, two quarts of methyl alcohol were consumed in a room of 1,500 cubic feet capacity in a formaldehyde generator, and, in addition, three pounds of commercial formaldehyde were exposed on the sheets. Three pints of ammonia water were then used. The method does not seem to interfere with the effectiveness of the fumigation.

Journal of the American Medical Association, March 30, 1907.

Lymphoid Changes in Infectious Diseases.—W. T. Councilman calls attention to the proliferative changes followed by necrosis taking place in the lymph nodes throughout the body in certain infectious diseases, but specially noticeable in certain regions. The necrosis occurs chiefly in the germinal centers, but there may also be destruction of small scattered lymphoid cells. The necrotic cells are taken up by phagocytes, which are greatly increased by proliferation of the endothelial cells of the sinuses. The new formation of cells does not, as normally, lead to increase in the small lymphoid cells. The new cell formation seems to start from cells of an indifferent character resembling those found in the germinal centers. Some of them seem simply to grow in size. Others are converted into plasma cells and some cannot be distinguished from myelocytes. Polynuclear leucocytes are not formed. These new cells enter into the blood, partly by means of the efferent lymphatics, partly by migrating into the vessels, and are found in blood-vessels of all tissues of the body, but they seem less adapted to the blood movement than the normal leucocytes. They are found in great numbers in the vessels of certain organs, such as the kidney, and they pass from the vessels by active ameboid motion into the interstitial tissues in such numbers as sometimes treble the weight of the organ. In the interstitial tissues the cells have a greater tendency to plasma cell differentiation than elsewhere, and foci may be found composed of typical plasma cells. The cells have marked power of proliferation and nuclear figures are abundant. In division, the cytoplasm becomes more granular and granules are cast off. Councilman has not been able to find a relation between these foci and injury or degeneration of the tissue. The interstitial foci are most frequently found in the kidney and next in the adrenals.

Meningism as Distinguished from Meningitis.—C. Jackson favors the use of the term meningism, introduced by French writers, to designate a syndrome with most of the earlier symptoms of meningitis, but without lesions of the meninges and of more favorable prognosis. Any of the symptoms of meningitis may occur, but the erethistic, rather than the depressive, predominate. The full development of pressure symptoms, paralysis or other indications of actual organic disease, will usually exclude meningism. He recognizes

as etiologic types the toxemic, the reflex, and the irritative; in all three there are [illegible] changes and in many cases direct action on the cortical cells. In the toxemic cases the nosotoxins in the blood act similarly to toxic drug doses on the cerebrum. The readiness with which the symptoms of meningism can be quieted by small doses of morphine is remarked on by Jackson as an important diagnostic point. These cases are distinct from Quincke's serous meningitis inasmuch as there is no serous involvement. Looking at the condition from the otologist's point of view, the irritative and toxemic cases, he says, when occurring in the course of middle-ear disease, are of the utmost importance as regards diagnosis, and often call for radical operation even if the mastoid is yet uninvolved.

The Radical Mastoid Operation.—F. Allport gives a detailed and very fully illustrated description of the radical mastoid operation, which, he says, is the acme of mastoid surgery, should only be undertaken by an operator of special experience, and is worthy of the continued study of the aural surgeon. He makes a long incision so as to expose a wide operative field and uses self-retaining retractors that check all soft tissue hemorrhage. Each stage of the operation is described in detail and special stress is laid on the proper after-packing of the cavities, for which he uses several pieces of gauze instead of a single one, as is done by some operators. The importance of the after-treatment is emphasized generally. He closes his paper with a quotation from Ballance against undue conservatism as regards this operation for the relief of intractable purulent otorrhea.

Spina Bifida.—H. Greenburg pleads for the more extended use of operative methods in the treatment of spina bifida, and reports a case, calling attention to certain points in the technique. He employed the muscle flap method of Bayer, improving on it, however, by utilizing the aponeurosis of the latissimus dorsi. A longitudinal incision of sufficient length to cover the defect was made over one side of the spinous processes above the cleft, thus freeing a section of the aponeurosis at its origin on that side. Another longer oblique downward incision was made from the upper point of the first, thus making a triangular flap of aponeurosis free at all points except the apex. Using this apex as a center, the whole flap is rotated downward until it covers the defect of the vertebra on that side. The same procedure is followed on the other side, and the borders of the flaps are united with chromicized catgut directly over the defect, giving a covering next to bone in strength and consistency. His patient, who had been getting steadily worse, began to improve and was nearly well in two months. The pressure on the cord, which had lasted for sixteen years, and had suspended the function of the cord, had not so impaired its tissue as to prevent a speedy alleviation of symptoms and restoration of function.

Arseniuretted Hydrogen Poisoning.—N. W. Jones gives the history of five cases of poisoning by arseniuretted hydrogen in workers with the cyanid process of gold extraction from low-grade ores, and also tabulates fifty-five other cases of poisoning from this gas collected in medical literature. Considering the very common presence of arsenic in the materials used in this process a rather frequent occurrence of such poisoning might be looked for, but these cases seem to be exceptional. It seems rather remarkable that so few cases of this poisoning from all sources are on record in view of the numerous possible sources in the arts and manufactures. Jones discusses the pathology, symptomatology, and treatment, and reviews the literature in regard to the effects on the system. The poison acts differently from the other salts of arsenic. The blood and kidneys are principally involved, the hemoglobin and red cells being attacked, and the kidneys undergoing an intense degenerative process mainly involving the convoluted tubules, and the glomeruli least. The three characteristic symptoms are pain in the region of the kidneys, hemoglobinuria, which is a constant symptom, and jaundice, probably obstructive, though the disturbed liver cell function, may play a part. Death when it occurs is undoubtedly largely due to acute urinary suppression. Some patients have shown uremic symptoms, but the majority do not. Twenty of the cases tabulated were fatal, death occurring in from two to thirty days, the average being 8.2 days. The chief indications in treatment are: First, abundant fresh air and administration of oxygen. Second, the production of free diuresis to prevent blocking of the uriniferous tubules with disintegrated blood cells and epithelium. Saline enemas and warm baths may also be useful. General supportive treatment [illegible] diuresis is a very favorable sign, as the majority of patients with polyuria recover. The consecutive anemia is much benefited by iron.

Inspection of the Jugular Vein and Visual Methods in Diagnosis of Heart-Block.—Arthur D. Hirschfelder criticises the recent contribution on this subject by G. W. McCaskey, Fort Wayne, Ind., who replies to the criticism. Hirschfelder fails to see what advantage McCaskey's ocular method of diagnosing heart-block by means of a specially devised apparatus has over simply watching the pulsation of the jugular vein while feeling the pulse in the carotid with the finger. He believes that mere inspection of the venous pulse, while sometimes of value, is subject to grave diagnostic error. In his reply McCaskey, while admitting that Hirschfelder's criticism is partly right, believes that in a large number of cases the use of his apparatus will be of great value in arriving at a diagnosis. He thinks there can be no question as to the greater ease with which comparison can be made between the venous and arterial pulsations by means of his apparatus as compared with the clumsier method of inspection and palpation. He thinks the whole question is whether these advantages are sufficient to offset the multiplication of instruments.

The Lancet, March 10, 1907.

Aceto-Salicylic Acid in Rheumatic Endocarditis.—A case history is detailed by E. C. Ibbotson, whose patient was a thin anemic girl of sixteen years, presenting the usual features of rheumatic endocarditis and being in a condition of extreme debility. Aceto-salicylic acid was used in fifteen grain doses, when the temperature showed a tendency to rise. It was later continued in seven grain doses thrice daily. In the author's view the case seems to point out the superiority of this particular acid in rheumatic fever when the salicylates have been tried without positive and permanent effect. He does not overlook, however, the value of the opium and blisters used in this special case. For a ferruginous tonic following the acute symptoms hemoglobin is less liable to produce relapse than iron salts in combating the subsequent anemia. He has found that salicylates aggravate epistaxis which in his experience is not by any means an uncommon concomitant of rheumatism, and is probably due to the accompanying anemia. It is important that the aceto-salicylic acid should not be given in tabloid form unless the tabloids are crushed before administration. The powder suspended in water with a little mucilage acts well and has no unpleasant taste. He has not found aceto-salicylic acid produce headache or dyspepsia, but, he thinks, that it is contraindicated in chronic rheumatism occurring in the subjects of organic heart disease of non-rheumatic origin.

The Medical Treatment of Congenital Pyloric Stenosis.—G. A. Sutherland gives detailed histories of three cases, two recovering and one dying without apparent cause. He then discusses in turn, the object aimed at by treatment, the food required and feeding methods, and gastric lavage. The aim of treatment is to keep the stomach free from irritants, which may maintain pyloric spasm and from anything in the food line which, digested or undigested, may excite such spasm. Signs of progress are cessation of vomiting, regular bowel action, less marked stomach peristalsis, cessation of discomfort, whining, apathy, etc., on the child's part, and improvement of nutrition. Diarrhea is a common complication during the course of treatment. The best plan here is to reduce the amount of food one-half and keep it so until the diarrhea has ceased. Half a grain of gray powder may be given twice or thrice daily. The diarrhea is always a serious symptom and may cause death. The author has found no results from antispasmodic drugs or opium even pushed to the full degree. In cases of marasmatic infants with pyloric stenosis, with all the tissues dried up, the use of saline injections both subcutaneously and per rectum has seemed beneficial. From four to ten ounces of normal saline solution can be given daily and will act as a restorative until the improvement of the pyloric function allows of the entrance of a sufficient amount of food into the system by the natural route. In cases in which the infant is much reduced or has a subnormal temperature brandy, up to half a dram daily, will be found of service as a general tonic. The administration of cod-liver oil by inunction, if it be of any value, would appear to be specially suited to the conditions present in this affection. The author has only employed it once and in that case a skin eruption quickly followed and led to its discontinuance.

Tertiary Syphilitic Fever and the Visceral and Other Changes Connected with It.—The paper of F. P. Weber

opens with the history of the case of a woman of 36 years who came under observation at various times, there being at each time a remarkably rapid disappearance of the syphilitic fever on the commencement within two days or so of antisyphilitic treatment. Such a fever can easily be mistaken for the pyrexia of sepsis or of tuberculosis. It has sometimes been mistaken for malaria. Other maladies requiring exclusion are typhoid, malignant endocarditis, and febrile cholelithiasis. The author passes in review the literature of the subject and refers to various cases in which local symptoms have pointed to the involvement of some definite organ or system, due to specific infection, the febrile movement being a prominent symptom. Under this category are mentioned enlarged liver with jaundice, dyspepsia, diarrhea, etc. Authorities seem to agree that it is in the cases in which the infection lodges in the portal system that the fever is particularly constant and prominent. It is often of an intermittent type and accompanied by shivering. One case is recorded of a man dying from intraperitoneal hemorrhage, which the autopsy showed to have arisen from a perforating syphilitic ulcer of the stomach. It must be acknowledged that while undoubted syphilitic gumma of the stomach and bowels is rare, a good many cases have been verified either by the results of treatment or autopsy.

British Medical Journal, March 16, 1907.

Intestinal Worms in the Vermiform Appendix.—J. W. Heekes refers to this subject in connection with an operation on a pelvic case in a woman of thirty-one years. As the appendix was elongated, swollen, and coherent, it was removed. After ligature of the stump a thread-worm was seen to wriggle out from the lumen of the appendix. On subsequently opening up the excised portion ten more were seen lying in the mucous membrane for about 1½ in. of its length; some were on the surface, one or two lay deep down in the lining membrane, but none had pierced the other coats of the appendix. On examination microscopically three were found to be male, and the remainder female, with ova in great numbers. The mucous membrane of the appendix was not much inflamed, but there was some congestion. Probably this was due to the pelvic peritonitis having involved the appendix and caused the adhesions. The occurrence of the worms in the appendix was most likely accidental, they having migrated from the cecum, for the patient had had the usual symptoms of the presence of thread-worms for about three and a half months. The history of the case pointed to old-standing trouble in the pelvis, especially on the right side, though at the operation the left Fallopian tube was also found adherent and swollen, and was removed. Three weeks before admission the patient had pain in the right iliac region, accompanied by vomiting, and the bowels were constipated, but there was no proof that this attack was of appendicular origin.

Class Incidence in Cancer.—D. Heron has made some investigations based on the English Registrar-General's returns and tabulates his results in this brief paper. It appears from his figures that there is always a substantial correlation between the cancer death-rate and social status; in other words, the evidence of cancer is most heavy among the well-to-do class. The author observes that what is badly needed at the present time is a collection of complete family histories of cancer cases. While such family histories in cases of insanity and pulmonary tuberculosis have been provided for the use of this laboratory in fair numbers, which we hope may go on increasing, we have, and can find, no records of any value bearing on heredity in cancer cases. The statements "a family history" or "no family history" are purely useless for scientific discussion of inheritance, when neither the individual relatives attacked nor the sizes of the families are stated.

The Relation of Diet to Thyroid Activity.—Experiments have been made by A. D. Fordyce in feeding rats on milk alone and on bread and milk, and comparing the thyroids removed from these two series of animals with those of wild rats. He found that the glands of all animals fed on bread and milk showed a constant picture, while those from the wild rats (caught at the same time and place), though showing somewhat wider variations, yet in all cases displayed in a greater or less degree the same nature of differences from both the preceding type of gland. In the milk-fed rat gland-sections showed large vesicles, well filled with colloid material, while the lining cells were small with deeply-stained nuclei. In the bread-and-milk-fed rats the vesicles were seen to be very markedly smaller and the amount of colloid present very considerably less. Whereas, in the case of milk-fed rats, each vesicle consisted of a large lumen surrounded by a narrow ring of somewhat flattened cells; here it consisted of a ring of columnar cells enclosing a minute lumen or lying apparently almost in contact. Examination of the glands of wild rats showed them to be of a more or less intermediate nature between those of milk-fed and those of bread-and-milk-fed animals. Compared with sections from bread-and-milk-fed animals, the vesicles appeared distinctly larger, they contained considerably more colloid material, and the lining cells showed a greater variation in shape. These glands, one and all, it must be remembered, were removed from animals clinically in perfect health; and, while the thyroid gland is an organ well known to be subject to considerable variations in structure, yet the interest in the present note rests in the fact that the variations in the series of glands examined corresponded with the differences in diet.

The Use of the Calcium Salts as Cardiac Tonics in Pneumonia and Heart Disease.—Lauder Brunton states that he was called to see a case of pneumonia, and, fearing that the heart would fail, he thought over all the remedies which were likely to avert such an unfortunate result. It then occurred to him that calcium chloride ought to be useful. The only harm it was likely to do was to increase the coagulability of the blood, but any risk of this sort was small in comparison to that from cardiac failure, so he prescribed it. It is not so easy to judge of the usefulness of calcium salts in theatened cardiac failure as it is of the action of oxygen and strychnine, because the results are not so immediately apparent. As the patient for whom he prescribed the calcium made a good recovery he was encouraged to give it again, and has done so in a considerable number of cases. In some of them a fatal result has ensued in spite of everything that could be done, but in a number of them the effects appear to him so encouraging as to deserve a wider trial for the medicine. He usually gives it in 5 to 10 gr. doses every four hours, simply dissolved in water. As it is very deliquescent it can only be kept in solution. It has a very disagreeable saline taste, but this is well covered by saccharine, one minim of the elixir of saccharine containing one-twentieth of a grain of saccharine is sufficient to cover the taste of 10 gr. of calcium chloride. This mixture may be given either in water or in milk, and it does not interfere with the use of any other remedies. He has also used it in cardiac disease, where the ventricular wall appeared to be losing power, and here also the results have been encouraging. In cases of pneumonia, where one wishes to get rapid action, he thinks the chloride is the best salt of calcium, but in cardiac disease other salts may be employed, such as the lactophosphate or the glycerophosphate. It is quite possible that the great benefit one frequently observes from a milk diet in cases of heart disease may be due, in part at least, to the large quantity of calcium salts which the milk contains.

Berliner klinische Wochenschrift, March 11, 1907.

Retropharyngeal Growths.—Litthauer reviews the literature of tumors in this situation and says that so far thirty-four such cases have been reported. He contributes to this number two of his own. One of these was a gumma which promptly subsided under the administration of potassium iodide, while the other was a fibrosarcoma measuring 9 cm. by 6.5 cm. by 5 cm. It occurred in a woman of thirty-five years and was removed through an incision running parallel to the left lower jaw and extending from the mastoid process to the hyoid bone. The patient made a good recovery though certain paretic symptoms such as weakness of the soft palate, dysphagia, etc., persisted. Among these symptoms the so-called Horner's symptom complex was conspicuous; this depends on paralysis of the sympathetic and comprises contraction of the pupil, narrowing of the palpebral opening and enophthalmos. From a consideration of the reported cases Litthauer concludes that the incision he made use of is the most advantageous and that attempts to remove retropharyngeal growths through the mouth or through a subhyoid pharyngotomy are ill-advised.

African Sleeping Sickness.—Kutscher contributes an account of what is known in regard to this infection. Formerly considered to be more or less confined to the western coast of Africa, Cook in 1901 discovered a new area of infection in British Uganda, on the shores of the Victoria-Nyanza, which since that time has been spreading rapidly in spite of all efforts made to restrict it. Clinically four stages of the disease may be dis-

tinguished. In the first, which extends from the date of infection with the trypanosomes to the onset of fever and the appearance of the eruption, no symptoms occur. Sometimes during this period it is possible to demonstrate the presence of trypanosomes in the blood or in the swollen cervical glands. This stage is of uncertain duration and is followed by the so-called trypanosome fever. This is characterized by irregular attacks of fever which are usually accompanied by severe headache and are often taken for malaria. Together with the fever transitory edema, erythema, and urticaria of the face and legs frequently develop. The heart rate and respiration are increased, and swelling of the spleen may be noted. The lymph nodes, especially the cervical glands, are swollen. This stage gradually merges into the third phase, the true sleeping sickness. The patients evince a tendency to fatigue, irritability, and neglect of the person; gradually the tendency to somnolence increases, it is difficult to persuade the patient to take the necessary amount of nourishment, and finally the fourth stage sets in, in the course of which a terminal secondary diplococcus infection of the cerebral membranes frequently takes place. It has been established that the infection occurs through the bite of a tsetse fly, the *Glossina palpalis*, and attempts at prophylaxis must be directed towards the extermination of this insect. The prognosis of sleeping sickness is extremely bad, although certain arsenic combinations and trypan red may be found to be satisfactory therapeutic agents.

Münchener medizinische Wochenschrift, March 5, 1907.

The Prophylaxis of Ophthalmia in the Newborn.—Seefelder speaks highly of the value of silver acetate as a substitute for silver nitrate as a prophylactic against ophthalmia in infants. The efficiency of this agent is as great as that of the nitrate, while it seems to have no disadvantages. In a series of 500 infants the author applied the acetate to one eye and the nitrate to the other and found that in no case were any evidences of irritation caused by the acetate. There was also no demonstrable damage to the corneal epithelium and the conjunctiva did not offer any indications of undue stimulation. He therefore considers that silver acetate is not inferior to the nitrate in its action, while it possesses the advantage that its solutions do not become more concentrated through evaporation, whereas, with silver nitrate, a change of this nature may lead to serious consequences.

The Effect of Cholin and of the X-Rays on the Course of Pregnancy.—Hippel and Pagenstecher review the literature of this subject which has now become quite large and also describe the results of some experimental observations of their own. They found on exposing pregnant rabbits to the *x*-rays that three sessions of fifteen minutes each were usually sufficient to destroy entirely or in great part the product of conception, but that individual variations in susceptibility in this respect were very great. It was also found that on covering the abdomen of the animal subjected to the action of the rays with a lead plate, the destruction of the embryos took place just about as when the rays were allowed to impinge directly on the unprotected abdomen. Fourteen animals were given injections of cholin; in ten of these sterility resulted, and in two others some of the embryos were destroyed. Only two of the animals were delivered normally, and both of these had received only small amounts of the substance. The authors state that apparently a daily injection of 10 c.c. of a one per cent. solution of cholin given for eight days, beginning with the sixth or seventh day after impregnation, almost always prevents the progress of the pregnancy. This result may also be obtained, however, even if the treatment is not given until much later. They consider it likely that the action of the *x*-rays produces in the body some toxic substance similar to cholin or to the derivative of the latter formed in the body which passes from the maternal body to that of the embryo and destroys the vitality of the latter's cells. The dead embryo then undergoes absorption and the changes in the uterine wall attending the pregnancy gradually retrograde. Cholin itself, if pure, appears to have no toxic effect on the maternal animal in the doses employed.

Deutsche medizinische Wochenschrift, March 7, 1907.

The Successful Inoculation of Calves with Bacilli from Human Pulmonary Tuberculosis.—Eber, who assumes the standpoint that human and bovine tuberculosis are due to the same etiological factor, describes two instances in which he was able to inoculate successfully calves with material obtained from cases of human pulmonary infection. In the one instance a portion of a phthisical lung was used and in the other a portion of the pia from a patient with pulmonary tuberculosis and tuberculous meningitis. These tissues were inoculated into guinea pigs and portions of the organs of the animals were used for the inoculation of the calves. Eber believes that these experiments do not prove that the two patients in question were suffering from a bovine infection and he expresses his disagreement with the alleged view of Koch and his pupils that all tuberculous lesions in man, which, on inoculation into the cattle prove to be virulent for these animals, were originally due to a bovine infection. The author's conclusions are assailed in another article by Weber, who discusses Eber's experiments and views and comes to rather different conclusions. The details of the controversy cannot be reproduced in brief.

French and Italian Journals.

Rupture of the Heart.—Leenhardt reports this case. The patient was a woman sixty-eight years old, and obese. She was attacked suddenly by intense pain over the whole left side of the thorax and by extreme dyspnea. No pathological antecedent could be discovered. The patient presented a condition of extreme asphyxia and great distress; the face was congested, the eyes bulged forward, the lips were cyanosed, and there was very violent pain in the precordial region, which the patient pressed with both hands; the pulse was very rapid and irregular. Auscultation of the heart was useless on account of the rapidity and irregularity of its action. Two hours later all of these symptoms diminished, and on the following day there was no sign of what had passed except a pulse which was a little more rapid than normal, beating 92 to the minute. The pain and dyspnea had completely disappeared. For three days this condition persisted and then suddenly more than seventy hours after the onset of the symptoms the patient sat up in bed, uttered a cry, and fell back dead. At autopsy the heart was found to be large and completely infiltrated with fatty tissue. The pericardium was distended by blood and clots. On the anterior surface of the left ventricle was a fissure communicating with the ventricles. The rupture of the heart was found to have been caused by an infarct.—*Bulletin et Mémoires de la Société Anatomique de Paris*, July, 1906.

Testicular Atrophy.—Achard and Demanche had a man sixty-eight years old under their care. The patient suffered from mitral insufficiency. There existed atrophy of the testicles, which had developed after a violent traumatism at the age of twenty-five years. This accident had been followed by a diminution of muscular activity and by a falling of hair. The patient's face was almost smooth, his hair of the head was extremely thin, and the hairs over the entire body were almost wholly lacking. The visage was pale and wan. The cheeks were pendent and the fascies recalled that of an old woman suffering from myxedema. After studying the case the writers suggest the possibility of a relation between testicular insufficiency and thyroid insufficiency.—*Gazette des Hôpitaux Civils et Militaires*, December 27, 1906.

Ferments in the Urine of the Child.—Angiola Borrino has made examinations of the urine of healthy children from a few days old to twelve years of age to determine whether the ferments of the gastrointestinal system, pepsin, and trypsin are to be found in the urine. Both are known to be found in the urine of adults. The author finds that a ferment analogous to pepsin is found in the urine of children of all ages, while a ferment analogous to trypsin seems to be absent. Uropepsin is found in nursing babies and the newborn. Other authors have found it in the stomach of the fetus.—*Rivista di Clinica Pediatrica*, December, 1906.

Primary Sarcoma of the Tendon Sheaths.—V. Gaudiana says that up to 1880 it was thought that sarcomata never occurred on tendons or their sheaths. It is now known that such tumors do occur, and the author describes one in a child of twelve years, occurring on the tendons of the long and short extensors over the first metatarsal bone of the left foot, the course of which was very malignant. These tumors occur at any age, on any tendon, and are in general rather small, lobulated, and soft, or hard according to the type of sarcoma present. Both the skin over the tumor and the tumor itself are movable, and the function of the part is not interfered with. The glands are not involved early, and metastases occur late in the disease.—*Il Policlinico*, December, 1906.

Traumatic Ruptures of the Perineal Urethra.—Operative Results.—Savariaud has practised three interventions for traumatic rupture of the perineal ureter. In the

first patient [illegible] ruptured and the ureteral mucous [illegible] of its inferior surface. He practised [illegible] of the ureter of the corpus spongiosum and completely closed the perineum. Healing took place by first intention, and when the patient left the hospital the caliber of the ureter was sufficient for the passage of a sound number forty-eight. Three years later the ureter admitted only a bougie number twenty one. In the second case immediate suture was not successful and several weeks later a new intervention was performed. The result is not known on account of the disappearance of the patient. In the third case a suture of the ureter was impossible on account of the condition of the ruptured extremities, the borders of which were slashed, consequently Savariaud attached the ruptured extremities to the skin and placed a sound in position for a few days. Bougies were then passed. The patient urinates with comfort, but in the perineum there is cicatricial block which is noticed when the smallest bougies are inserted.—*Revue de Chirurgie*, December 10, 1906.

Pubiotomy.—Gigli believes that we have arrived at a new era in obstetrics owing to the important and precious discovery of pubiotomy. He thinks that he has reached the method of cutting the pelvic ring that gives the best possible prognosis, because it involves separation at the most favorable point of the pelvis, that point which results in the least danger of infection, the quickest healing, and the firmest union. He hopes to be able to convince his colleagues that symphyseotomy, exposing the woman to grave dangers of infection and of inability to walk as it does, has no right to exist, and that they will all desist from performing it and use his method. He reports a series of 300 cases of pubiotomy with a mortality of three per cent., and the cases that were fatal were all infected before the operation. If we leave out these cases we have a mortality that is reduced to zero.—*La Riforma Medica*, December 8, 1906.

Temporomaxillary Actinomycosis Cured by Iodo-Gelatine.—Francesco Lupo published the history of a case of actinomycosis of the temporo-maxillary articulation and side of the jaw, occurring in a woman of twenty-eight years of age. The swelling was of woody hardness, and examination of the pus from softened areas showed the presence of actinomyces and the absence of any other pus germs. They were in abundance in all pus examined during the second year of the disease. Each granule consisted of a central mass of filaments and a peripheral mass of rays. Cultures in animals showed foci of actinomycosis. The neighboring glands showed a characteristic hyperplasia with foci of detritus similar to cheesy matter. The patient was treated with iodide of potassium internally and with injections of the iodo-gelatine of Sclavo. The result was a complete disappearance of the growth and of all symptoms except an ankylosis of the jaw due to a large amount of cicatricial tissue in the articulation. This was removed by operation and the patient recovered the use of the articulation.—*Rivista Critica d. Clinica Medica*, December 1, 1906.

Hypodermic Injections of Sea Water.—P. Schivardi describes the use of injections of sea water for scrofula, tuberculosis, and similar conditions, which has been attempted since 1904. As used at present the water is obtained in the deep sea, far from any river, and will keep pure for some days. It must be sterilized before use and diluted with freshly prepared distilled water. One part of sea water is used to three parts of distilled water. It has been found better to use small injections daily rather than larger ones at longer intervals. The temperature of the injections should be that of the body, and syringes of metal or rubber should not be used. Five or ten centigrams of isotonic marine serum are injected at once. There is no reaction, but thirst is produced which produces diuresis. The best place for injections is the anterolateral region of the abdomen. Aseptic precautions are observed, and local massage follows. The results of such treatment have been most encouraging.—*Gazzetta Medica di Roma*, November, 1906.

Treatment of Heart Disease by Removal of Chlorides.—R. Massalongo and G. Zanibelli have made use of a diet that limits the ingestion of chlorides in cases of heart diseases for several years with gratifying results. They conclude that the chloride of sodium is a regulator of the isotonia of the humors, of osmotic pressure, of the dehydration of the tissues, and of arterial pressure, but at the same time is a factor in asystolic phenomena and dropsy in cardiac diseases. In the period lack of compensation there is a constant retention of the chlorides and hydration of the tissues, and a diminution of the chlorides ingested soon restores the equilibrium and puts an end to the unfavorable symptoms. Diagnostic and prognostic information can be gained by experimenting with the diet in this direction. [illegible] diet poor in chlorides must often be supplemented by the use of diuretics or heart tonics which accelerate the circulation. The diet is diuretic and regulates the circulation because the removal of edema lessens the obstacles to the heart action, and indirectly increases the energy of the heart. It has an important suspensive action, preventing asystolia, and it has not only a regulating and dishydrating action, but an energetic disintoxicating effect, retarding uremic symptoms.—*La Riforma Medica*, December 8, 1906.

Book Reviews.

TREATISE ON ORTHOPEDIC SURGERY. By ROYAL WHITMAN, M.D. Third Edition, Revised and Enlarged. Philadelphia and New York: Lea Brothers & Co., 1907.

DR. WHITMAN'S book has met with a very appreciative reception, as shown by the succession of editions within a comparatively few years. The subject is presented, as far as possible, in an objective manner, and the space allotted to each individual topic has been determined primarily by its relative importance in the actual work of orthopedic clinics. Particular attention has also been given to methods of examination, to symptoms, and to the causes and effects of disease and disability, so as to indicate in natural sequence the principles of treatment. The book is in many respects a personal record of the writer's experience, particularly as regards treatment. The illustrations, which are of uniform excellence, are also taken largely from the material at the author's clinics and hospital service and constitute a very important addition to the text. The good opinion expressed with regard to the worth of previous editions may be repeated here and the work labeled as a thoroughly up-to-date treatise on a most important subject, a proper knowledge of which is essential to every practitioner of medicine.

CLINICAL LECTURES ON ENLARGEMENT OF THE PROSTATE, With a Description of the Author's Operation of Total Enucleation of the Organ. By P. J. FREYER, M.A., M.D., M.Ch. Third Edition. New York: William Wood & Co., 1906.

THESE lectures constitute a portion of the work which the author intends to publish at a later date on the "Surgical Diseases of the Urinary Organs." The most important part of the book is taken up with a description of the writer's operation for total enucleation with which his name has been closely associated and which he had done in over three hundred cases up to the date of publication. Of the 312 cases 290 were successful to the extent that the patient was able to retain or pass urine without the aid of a catheter. The mortality in this series was about seven per cent. In the concluding chapter is presented a brief discussion of the claims of the writer in opposition to those for a similar operative procedure made by Fuller of New York, which is shown, however, to be totally different. The book presents the subject of prostatic hypertrophy and its treatment by local enucleation in a very clear and systematic manner, and constitutes a valuable guide to a procedure which has gained greatly in favor since its introduction.

MINOR MALADIES AND THEIR TREATMENT. By LEONARD WILLIAMS, M.D., M.R.C.P. Physician to the French Hospital, etc., London. New York: William Wood & Co., 1906.

THE subject matter of this book consists of a series of lectures delivered at the Medical Graduates' College and Polyclinic in London by the author, and the object in publishing them in the present form has been to supply in an accessible shape detailed information on topics with which the ordinary text-book deals only in a cursory manner. The book is very comprehensive in scope, dealing with the maladies which are liable to be of every-day occurrence, with numerous hints as to their differential diagnosis and the treatment. In a chapter entitled "Change of Air," there are reviewed the principles of climatology and spa treatment, and another chapter presents the main principles of domestic and personal sanitation. There is also an excellent concluding chapter on the subject of insanity, in which are given the practical and legal aspects of the matter. Taken as a whole, the work is a very efficient little manual, although the detailed references to certain forms of medication and treatment will not always appeal to the American practitioner. There is an excellent and complete index.

ON RETROPERITONEAL HERNIA; Being the "Arris and Gale" Lectures on the Anatomy and Surgery of the Peritoneal Fossæ, delivered at the Royal College of Surgeons of England in 1807 by B. G. A. MOYNIHAN, M.S., F.R.C.S. Second Edition, Revised, and in part rewritten by the author and J. F. DOBSON, M.S., F.R.C.S. New York: William Wood & Co., 1906.

THE advances which have been made in the anatomy of retroperitoneal hernia since the first publication of these lectures in 1899 have made imperative certain changes of opinion, and this has necessitated a number of important changes in the present edition. Within less than two hundred pages is given a very comprehensive idea of a subject which received comparatively little attention until within recent years. After describing the development of the intestinal canal and peritoneum, a knowledge of which is most essential to the understanding of the [illegible], the writers take up the various hernia which may occur in the duodenal folds and fossæ, the folds and pouches in the neighborhood of the cecum and vermiform appendix, the intersigmoid fossa, and the lesser peritoneal sac. A number of illustrative cases of the various types of hernia referred to are appended.

ANALYSE DES URINES. Considérée comme un des éléments de diagnostic. Par le Dr. ERN. GÉRARD, Professeur a la Faculté de Médecine et de Pharmacie de Lille. Deuxième édition revue et augmentée. Paris: Vigot Frères, 1906.

THE title of this book fully indicates its nature. The author has endeavored to create a work which should fill a want which does really exist. To students not familiar with the French as distinguished from the German view of some of the questions discussed, perhaps the book will appear somewhat peculiar; but as the modern English and American pathology is so distinctly German, an acquaintance with other views may be of value. Really original work in this department of study is hardly possible, yet a careful study of this book may have its reward.

ATLAS AND TEXTBOOK OF HUMAN ANATOMY. By Dr. JOHANNES SOBOTTA, Professor of Anatomy in the University of Würzburg. Edited, with additions, by J. PLAYFAIR MCMURRICH, A.M., Ph.D., Professor of Anatomy in the University of Michigan. Vol. I, Bones, Ligaments, Joints, and Muscles. Vol. II, the Viscera, Including the Heart. Philadelphia and London: W. B. Saunders Company, 1906.

THIS is a translation, with notes and additions, of Professor Sobotta's well-known and valued anatomical atlas. It differs from the original, however, in that the atlas has been combined with the text, instead of the two constituting separate parts. We question the wisdom of this, for the work was intended chiefly for consultation, and not as a textbook for the undergraduate, who has better works for his purpose in Cunningham and Gray. In the original the atlas first contained the illustrations with only the absolutely essential descriptive matter. The text might, indeed, almost as well have been omitted as far as the utility of the work to the majority of those who will use it goes. This does not mean that the text is not good, but it is in the way of the man who wants only to sharpen the lines of his mental picture of a certain anatomical region which may have faded a little since his dissecting days. The inclusion of a description of the heart among the viscera in this second volume is perhaps anatomically justifiable, but we think it would have been better to follow the usual custom of describing the heart with the rest of the circulatory system, which will presumably form part of the subject matter of the third volume of the work. The illustrations, of which there are 320 in the first volume and 214 in the second, are exquisitely beautiful and of photographic accuracy, those of the bones especially being extremely well done. They are mostly lithographs printed in colors. In the pictures of the bones of the skull the plan has been adopted of giving each of the bones a color of its own, so that in the topographical views of the cranium one distinguishes the different bones with ease. The Basle anatomical nomenclature [BNA] has been employed for the most part, though many of the terms (except those in the section on myology) have been anglicized. The translation has been well done by Dr. W. Henry Thomas.

PROGRESSIVE MEDICINE. A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences. Edited by HOBART AMORY HARE, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College, Philadelphia. Assisted by H. R. M. LANDIS, M.D., Assistant Physician to the Out-Patient Medical Department of the Jefferson Medical College Hospital. December 1, 1906. Philadelphia and New York: Lea Brothers & Co., 1906.

THE December number of this quarterly digest is on the same plan as heretofore, and it is also up to its own high standard of excellence. In the present volume Dr. Steele considers diseases of the digestive tract and allied organs, the liver, pancreas, and peritoneum; Dr. Belfield contributes the section on genitourinary diseases; Dr. Bradford writes on the diseases of the kidneys; Dr. Blodgood devotes one hundred pages to the consideration of anesthetics, fractures, dislocations, amputations, surgery of the extremities, and orthopedics; and, finally, Dr. Landis supplies a therapeutic referendum. All of these contributions are useful, and the busy practitioner can here find whatever is of value in the periodical literature of the past year or more. Further, the judicious work of the editors of the various sections saves the busy reader the trouble of sifting the wheat from the chaff; only the former is here presented.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held March 1, 1907.

DR. JOHN F. ERDMAN IN THE CHAIR.

Hernia of the Bladder.—Dr. WM. A. DOWNES presented a man, fifty four years old, who had had a hernia for a number of years, and who was admitted to the hospital December 24 and operated on December 31. His hernia had not given him trouble until one or two years ago, when he had to get up six or seven times at night to empty the bladder. During the day he had no such trouble. The sac was opened on the upper and outer side; in so doing the lower and inner portion showed the usual characteristics of bladder hernias, a great deal of peritoneal fat. In stripping off this fat he tore a three or four inch hole in the top of the bladder. He introduced his finger and found at least two-thirds of the bladder in the hernial sac. The finger went to the trigone, and it was evident that the greater portion of the bladder was in the hernia right along. A cigarette drain was introduced and a catheter passed through the urethra into the bladder; this latter was kept in five days. The patient was discharged in three or four weeks without trouble, and without any leakage. There was a prompt healing of the wound. Dr. Downes believed that hernia of the bladder was more common than generally supposed. In three years he had had 110 adult hernias; four of these were of the bladder. One was in a femoral hernia, the other three in a direct inguinal hernia.

Case of Bilateral Goiter.—Dr. JOHN F. ERDMAN presented this patient for Dr. Frauenthal. The patient was twenty-four years old. He started general anesthesia and at the first whiff of the laughing gas she went into complete asphyxia. The operation was done then without any anesthetic, the patient feeling absolutely no pain whatever. When he removed the left lobe he found the trachea was angulated and he then removed the right lateral lobe. Evidently the parathyroids were not removed, for the patient had not suffered from myxedema at all. She also had a large fluctuating vascular growth upon the right thigh.

Dr. TOREK said that it was interesting to hear that the asphyxia was noticed before the operation. The cases in which asphyxia happened during anesthesia were usually the ones that presented asphyxia before operation. He recalled a disagreeable experience he once had in a case of carcinoma of the thyroid on which he wanted to operate. The narcosis had just begun when the patient died from asphyxia. The operation was to be done to relieve the asphyxia. Since that experience he had been hearing again and again of cases in which asphyxia in goiter cases occurred before and with the administration of the anesthetic; the inference was that if a patient with goiter had asphyxia an anesthetic should not be given.

Amputation of the Leg by Bier's Method.—Dr. A. V. MOSCHCOWITZ presented a man whose leg had been amputated by Bier's method for Raynaud's disease, with absolutely bad results, violating every rule both of commission and of omission, calling for a perfect result. The scar was upon the end of the stump and was made up of granulation and cicatricial tissue. The flaps had been made large enough, but they sloughed. The scar was adherent to the bone. The stump was absolutely painless. X-ray pictures of the stump were shown.

Myxofibroma of the Duodenum; Pylorectomy with Partial Atypical Duodenectomy.—Dr. A. A. BERG presented a man, thirty-seven years old, who had been referred to him by Dr. Basch, with a history of ulcer and with the physical signs of ulcer at the pyloric end of the stomach or first portion of the duodenum. Dr. Basch was inclined to the latter view. Inasmuch as extensive internal treatment had not yielded satisfactory results in the relief of the symptoms, Dr. Basch had proposed that operative therapy be carried out. The patient was sent to Mt. Sinai Hospital, where Dr. Berg opened the abdomen and found the pyloric end of the stomach, the first and second portion of the duodenum, the gall-bladder and under surface of the liver and head of the pancreas fused into one mass about half again as large as a hen's egg. There were numerous adhesions surrounding the gall-bladder, first and second positions of the duodenum and stomach. Some glands in the gastrohepatic omentum were infiltrated. The case promised to be a very difficult one because of the dense adhesions. The adhesions between the gall-bladder and first and second portions of the duodenum were first divided. In trying to separate the adhesions here it was necessary to separate the portal vein and common bile duct from the tumor. With sharp dissection he was able to get to and ligate the gastric and the left gastroepiploic artery, thus making it easy to approach the posterior aspect of the tumor from the gastric rather than from the duodenal side. The tumor mass was finally exposed and removed. On macroscopical examination it apparently was a carcinoma. A gastrojejunostomy was performed. The anesthesia was not well taken and the patient developed a capillary bronchitis, thus prolonging convalescence. The histological examination of the mass showed it to be a myxofibroma and probably was secondary to ulcer of the duodenum.

Dr. BASCH said that this case illustrated the difficulties of diagnosis and rather impressed upon the internist the necessity for early operation. Dr. Basch then gave the medical history of the case.

Pyloric Tumor, with Acute Dilatation of the Stomach; Pylorectomy.—Dr. A. A. BERG presented a man, thirty-six years old, a painter by occupation, who had been admitted to Mt. Sinai Hospital six weeks before. For two years previous to the present illness he had had occasional attacks of abdominal cramps, with loose movements of the bowels due to lead poisoning. There was no loss of weight, no history of syphilis or of gonorrhea. His present illness came on three weeks before his admission. The initial symptoms were intermittent burning pains across the upper portion of the abdomen. They lasted one week, and during this week there was no vomiting. The bowels were moved by enemata. After the first week vomiting set in and the bowels became constipated. The pains continued to be severe, but were relieved by vomiting or when the stomach was washed out. During the last week of illness prior to admission to the hospital the bowels had not moved and no gas was expelled. He vomited a yellowish-green fluid. On admission he was given ox gall, with the result that he passed some gas, but no fecal matter. The physical examination made by Dr. Moschcowitz showed that there was a large central prominence in the abdomen surrounded by a depressed area in the perhiphery. There was a wave and splashing sound. The stomach tube introduced produced two gallons of this yellowish-green fluid. When this fluid was removed the tumor could be felt in the epigastric region. A diagnosis was made of a pyloric tumor constricting the pylorus and giving rise to an acute dilatation of the stomach. Five days after admission operation was performed. There was found a hard nodular tumor, occupying the pyloric region of the stomach and the first portion of the duodenum. There was an extensive glandular involvement. The excision of the mass was comparatively easy. A gastrojejunostomy was performed with Murphy's button. The middle colic artery was often injured in these operations, and, if there were adhesions present, it was hard to avoid it.

Case of Fracture of the Upper End of the Radius.—Dr. CARTER S. COLE presented this patient to illustrate his paper. The patient was a man, a 'cello player and teacher,

who came to him with a condition beautifully shown by excellent plates and prints made by Dr. Caldwell, showing the head of the radius broken into several pieces, and with a quadrilateral fracture in the ulna. The only thing that could be defined by the first examination immediately after the injury was that there was a fracture of the head of the radius, a fracture of the ulna, a displacement of both bones backwards, and considerable extravasation about the joint. His first course was to restore the parts as nearly as possible to their proper position, put on abundant absorbent cotton, with a firm compression bandage, and over this a plaster-of-Paris bandage, the forearm being at a right angle and slightly pronated. His anxiety about the ulna, his fear of losing both flexion and extension, as well as pronation and supination, if any operative measure was taken, made him conclude that he would do nothing except to keep the parts in best possible position until the ulnar fracture had united; and if he then found that flexion and extension were prevented by the fragments of the radial head, he would remove the latter. Following his usual custom, he waited for six weeks, changing the plaster from time to time as the effusion got less and the splint became loose, and then, under an anesthetic, he tried flexion and extension. The adhesions yielded with very little effort and he satisfied himself that this function in time would be perfect. The accident occurred in May. In August he had already begun to play his 'cello with his orchestra, and from October until the present time he had played from four to seven hours daily. The splendid function was demonstrated by his playing the instrument before the Section.

The Adequacy of Local Anesthesia in Inguinal Hernia Operations.—Dr. JOHN A. BODINE read this paper. He said that modern surgery advised a patient with inguinal hernia to submit to operation for cure and in lieu of this curative advice the patient accepted his hernia and a truss. The surgical proposition of 90 per cent. cured, with short detention from business and small danger to life, would seem attractive for the relief of such a condition to persons who were suffering a 15 to 50 per cent. loss of earning capacity and were exposed to the danger of potential death, yet the number of trusses worn attested the universal rejection of this proposition. General narcosis, with its small but certain danger to life and its disagreeable features, presented a deterrent factor to accepting a surgical cure of hernia. If they eliminated the danger, the dread and the disagreeableness of general narcosis, they might turn a conspicuous surgical defeat into a colossal victory. In the earlier operations an effort was made to cocainize the ilioinguinal, the iliohypogastric, and the genitocrural, but it had been found that cocainization of the ilioinguinal alone, with infiltration into certain sensitive areas, sufficed for a painless dissection. The technique had been explained in previous papers. If the skin and subcutaneous tissue were properly infiltrated by a 1 to 500 warm cocaine solution, the incision down to and through the external oblique aponeurosis was totally devoid of pain. But few blood-vessels and nerve filaments were encountered in the incision to and through the external oblique, if the incision was not carried to or below the level of the external ring. At this latter point the ilioinguinal nerve expanded into many filaments and the bleeding points were numerous. It was, therefore, essential to find and cocainize the ilioinguinal trunk before incision into this level. After cocainizing the ilioinguinal at the upper limit of the hernia incision the operation in simple cases could be completed without additional analgesia and with little or no complaint of pain. Infiltration was necessary into the internal oblique around the arching fibers of the internal ring and around the sac neck during its dissection in the margin of the opening. Not one of the patients he had operated upon had given any evidence of either acute or moderate pain. None had grumbled or complained during the operation. Patients were often willing and even desirous of having the second side operated upon at one sitting. To each and every one of the double cases general narcosis was offered as a test at the second operation and refused. As the patient was flaccid, quiet and uncomplaining, there was no temptation to shorten or curtail the operation. That a solution of cocaine, amounting in sum total to any fractional part of a grain intermittently injected during an hour of time, was less dangerous than cerebral narcosis for the same time was obvious, and that it was entirely without danger to the patient was probably a fact. There was at times a set of symptoms once regarded as toxic manifestations of cocaine, sweating, pallor, and sighing, but they were purely psychic and in no way toxic. Fat presented the principal limitation to the method. The chief difficulty was in the necessary retraction for excision in a wound so deep. Age and lesions of the kidney and of the heart offered no barrier. In strangulated hernia local analgesia rose almost to the dignity of an imperative method. The added shock of an hour under cerebral narcosis, the danger from drowning in fecal vomit and the hurried decision as to whether a loop of gut should be excised or not, accentuated the advantage of a method that did not shock, which permitted the patient to control the vomit, and gave any quantity of time to decide on the circulation in the gut. There were certain advantages associated with local analgesia. It imposed upon the surgeon respect for tissues, gentleness of manipulation amounting to daintiness. Blunt dissection, tearing or rubbing the sac from the cord with gauze pads was impossible. Clean-cut dissection was necessary from beginning to end. The signal advantage of this method was the preservation of the structural integrity of the nerves in this area. Thinning, atrophy and paralysis followed division of a nerve trunk as an inexorable law, and this must to a greater or less extent follow injury to the ilioinguinal or hypogastric. This thinning or atrophy invited recurrences. A personal experience of over 400 operations for the radical cure of inguinal hernia with local cocaine analgesia formed the basis of his remarks. Since his first operation of this series no case of inguinal hernia had been operated upon under any other kind or method of analgesia. Consequently his experience embraced nearly all variations of the simple hernial protrusion and nearly, if not all, the different types of patients. In conclusion he believed that local analgesia was entirely adequate for the radical cure of inguinal hernia. In his 400 cases he had not had one instance of suppuration.

Dr. BROOKS H. WELLS, Dr. SCHLEY, Dr. FOOT, Dr. BERG, Dr. MOSCHCOWITZ, Dr. DOZANE, and Dr. DOUGLAS discussed the paper.

Dr. Bodine closed the discussion.

Fracture of the Upper End of the Radius; Some Personal Experiences with Radiographs and Plates.—Dr. CARTER S. COLE read this paper. For ten or twelve years he said he had been taught, read, and believed that fractures of the head of the radius were exceedingly rare, and that fractures of the neck of the radius were hardly possibilities. But he admitted that with the added means of diagnosis, the *x*-ray, a different conclusion could have been reached in some of the cases that passed under his observation. During his interne service at Chambers street (of sixteen months) no such fracture was recognized by any one, and a service of more than two years at Hudson street failed to bring to his notice any injury of this kind. A practically continuous service at the Post-Graduate Hospital for fourteen years did not furnish the desired and long-sought-for lesion until about three years ago; and then within a short time the several cases reported came under his observation. Dr. Cole believed that without *x*-ray examination the best they could do in the matter of diagnosis was to say that they had a fracture; to that they might add whatever seemed to be the prob-

able carpal. Their diagnosis was made on pain and crepitus upon rotation of the radius, together with pain on pressure about the radi ulnar articulation, and in individual cases there might be slight deformity. There was at first very little limitation to rotation, and there might be or not distinct crepitus or simply a click; the limitation to extension or flexion might not be worthy of consideration; but later the loss of rotation was considerable if not complete and was necessary to a diagnosis if neither a fluoroscopic examination nor an *x*-ray picture was available for that purpose. His conclusions were as follows: (1) In fractures of the head of the radius treatment by plaster-of-Paris circular bandage, the forearm flexed to a right angle and carried just a little beyond midpronation in the direction of pronation, the elbow joint having first been liberally surrounded by absorbent cotton held in place by a firm muslin bandage. Later, if sufficient interference be caused by any fixation sufficient to justify operative measures, removal of the fragments, and an effort to restore the function of the joint might be made. (2) In fracture of the neck immediate removal of the fragments, as fixation and loss of function must follow under any form of treatment. The same treatment was all the more imperative if fracture of the neck was complicated by fracture of the head. (3) If the ulna was fractured at the same time, avoid any open operative interference until a sufficiently long time had elapsed to show what permanent loss of function had been sustained and what probable improvement could be obtained without operation.

Dr. Foot, Dr. Bissell, Dr. Gallant, Dr. Morehead, and Dr. Frauenthal discussed the paper.

Dr. Cole closed the discussion.

A New X-Ray Table.—Dr. M. L. Kakels presented this. (See page 586.)

THE WILLIAMSBURG MEDICAL SOCIETY.

Stated Meeting, Held March 11, 1907.

"Some Middle Ear Dont's for the General Practitioner."—Dr. John E. Sheppard read this paper. Although the subject was an elementary one, it was frequently necessary to recall to one's mind some of the things already well known. Ear-drops of all kinds, from sweet oil and laudanum to solutions of cocaine, were to be avoided. Flaxseed poultices usually did harm. The best household remedy for earache was dry heat. If more heat was required, it was obtained by filling the external auditory canal with hot sterile water (112° to 120°) and placing the hot water bag on top of it. A patient was not to be allowed to suffer from an unrelieved earache any longer than was absolutely necessary. Early incision of the drum was the best preventive for mastoiditis, and was the most likely means to insure a speedy return to the normal hearing. A few hours after the ear began to run, pain should cease, and almost always did cease, unless the mastoid was inflamed. When the pain continued, it was necessary to investigate the mastoid for tenderness, and if this was found, the question of operation was not to be postponed too long. The late symptoms of mastoiditis (edema and redness behind the ear) were not to be waited for, as they indicated that the infection had already made its way through the external mastoid cortex, and that there was a beginning subperiosteal abscess. Waiting for the perforation of the external cortex gave equal opportunity for the perforation of the internal cortex, with the resultant intracranial complications. The occurrence of a mastoiditis without discharge from the ear was not infrequent. The appearance of pyemic symptoms in the course of, or following, a middle ear suppuration probably signified a lateral sinus infection. It was not to be overlooked that an otherwise unexplained high temperature in infants, or a sudden increase of fever in various diseases, might indicate middle ear involvement. The significance of mouth-breathing in relation to middle-ear conditions was not to be forgotten. It was in itself a symptom, not a habit. In adults it meant adenoids, deflected septum, hypertrophied turbinates, etc. In children it almost always indicated adenoids, and these were undoubtedly the cause of the majority of the ear troubles of childhood. They were also the cause of most of the cases of incurable middle-ear catarrhal deafness of later life. The remark was not to be sanctioned that the removal of adenoids was a fad. It was profitable to solve the problem of how to prevent their occurrence. Probably the lack of humidity in the atmosphere of the average living room was the cause of the development of adenoids. The use of the nasal douche in any of its forms was not to be countenanced.

Catarrh of the Upper Respiratory Tract.—Dr. Charles W. Stickle read this paper. He dwelt particularly on the suppurative conditions of the nasal accessory sinuses. Patients complaining of symptoms of hawking and spitting from a continual dropping in the throat, of difficulty of breathing through the nose, of hoarseness, deafness, of headache or other neuralgias, and of other disagreeable symptoms, were frequently treated to no avail for catarrh, and merely advised to use the nasal douche, or spray, or given astringent drugs, or sent to a high, dry climate. Their condition grew worse and worse, until they died from some sequela of an original infected mucous membrane in one or all of their accessory sinuses. Owing to the fact that in infants these sinuses were not developed, any purulent nasal or pharyngeal discharge was in the majority of cases directly due to the presence of pharyngeal adenoids. Ninety-eight per cent. of the benign purulent inflammations of the nose were summed up in the words "sinus empyema." It was the modern opinion of the majority of rhinologists that any discharge of pus, whether in the form of ozena or of ordinary pus streaks, was symptomatic of nasal accessory sinus necrosis, unless it was due to tuberculous or syphilitic ulceration of the nasal septum or lateral sinus. The pus issuing from the nasal sinuses was capable by direct contact or by means of systemic absorption, or local degeneration, of causing, first, the vasomotor inflammations in the nose itself, appearing most frequently under the form of frequent or continuous attacks of coryza, middle-ear abscess and its sequelæ, gastrointestinal derangements from the absorption of pus, thickening of the posterior wall of the larynx causing hoarseness, with subacute inflammation of the surrounding tissues, merging into a tracheitis, bronchitis, or bronchiectasis. Eye symptoms almost always accompanied sinus inflammation. What was to be expected when the pus was pent up in the accessory sinuses? First, and most to be feared, was meningitis. Epilepsy had been reported as due in some cases to sinus suppuration, with malformations and pressure of the nasal septum and turbinates. The etiology of sinus disease was clear; it resulted from the extension from the mucous membrane of the nose during the course of a simple coryza, of pneumococcic staphlycoccic, or streptococcic infections. The treatment was operative.

Early Diagnosis of Carcinoma of the Breast.—Dr. Adolph Bonner, in this paper, said that the importance of early diagnosis was seen in the fact that late surgical interference had negative results, and that 75 per cent. of neoplasms of the breast were carcinomatous. Tumefaction was the first evidence of carcinoma, which most frequently involved the upper outer quadrant. The tumor was hard, its border ill-defined and immovable in the surrounding tissues. Pitting of the skin and retraction of the nipples were early signs. Radiating and lancinating pains were sometimes early symptoms, but were never likely to occur while the tumor had acquired some size. Fibroma was found earlier in life, and though hard was well defined and movable in the surrounding tissues. The skin was not adherent. The pain was intermittent in character and aggravated at the menstrual period. Adenoma occurred at

the age of functional activity of the breast, and the tumor was well defined and lobulated, and the skin over it freely movable. Lipomata, chondromata, and echinococcus were rare. Diffuse hypertrophy was found early in life and associated with pregnancy. Gummata were rare, but when found were superficial, with early discoloration and ulceration of the overlying skin. Deep gummata underwent early breaking down and ulceration and were not well defined nor movable in the surrounding tissues. In the test of treatment it was to be remembered that iodides and mercury caused a transitory arrest in the growth of carcinoma. Tuberculous mastitis was rarely primary. In chronic mastitis the tumor was irregular and immovable, and never involved the glands. Its chronicity and the tendency to retract the nipple made it hard to differentiate between chronic mastitis and scirrhus carcinoma. Methodical physical examination included a determination of the relative size of the breasts; color of the skin, and its character, whether smooth, nodular, dimpled, drawn, or ulcerated; character of the nipples, whether on the same level, prominent or retracted, or offering the same resistance on traction. In palpation the breast was immobilized with one hand and the tumor moved in the direction of the fibers of the pectoralis major with the other, in order to determine the question of its attachment or not. At the same time consistency, size, and shape were determined. With the patient's arm adducted, the glands at the lower outer border of the pectoralis major muscle were next examined, the physician's finger tips pressing with an upward and downward motion into the axilla. Suspicion of carcinoma justified early incision.

Joint Meeting of the Chicago Medical and Chicago Pediatric Societies.

At a joint meeting of these societies, held February 27, 1907, there was a symposium on "Scarlet Fever." Dr. Ludwig Hektoen discussed the etiology and pathology of the disease, and from the facts he presented we are justified in concluding (1) that the predominant feature of the bacteriology of the throat in scarlet fever is the constant presence of large numbers of *Streptococcus pyogenes*. (2) That the overwhelming majority of the so-called complications and of the deaths in scarlet fever is due to invasion of the tissues and the blood by this microbe. (3) That in scarlet fever, even when mild, the organism gives evidence of systemic reaction to streptococci by variations in the streptococcus opsonic index, and probably also by the formation of streptococcus agglutinins. There is, therefore, no escape from the conclusion that *Streptococcus pyogenes* or some form thereof plays a most significant part in the scarlatinal process, but the author did not think that we were ready to take the final step and conclude that scarlet fever was wholly a streptococcus disease. Dr. Heman Spalding discussed the prophylaxis of scarlet fever, and said that in considering preventive measures it should be borne in mind that scarlet fever is not so generally infectious as measles or smallpox. In a community of susceptibles—those never having had the disease—about 38 per cent. will contract the disease when exposed to it, whereas in a like community about 90 per cent. would contract smallpox or measles if exposed to those diseases. As to the manner of transmission, the proof is strong that the infection can be conveyed through the milk supply. Fruit and vegetables peddled from a house where scarlet fever exists can be the means of spreading the disease. The prophylaxis of scarlet fever consists in separating the sick from the well and destroying all infection emanating from the scarlet fever patient. He emphasized strongly the point that after scarlet fever the entire house should be disinfected. Dr. John M. Dodson, in discussing the clinical history and diagnosis, presented a summary of the course and symptoms of scarlet fever as presented in 300 cases treated at the Memorial Institute for Infectious Diseases. He described the course of the usual type of moderate severity, and then noted the distinctive features of the more severe forms of the disease. Dr. M. P. Hatfield, in speaking of atypical cases of scarlet fever, said that he was distrustful of vomiting as a pathognomonic symptom of the disease. One should not rely too much on the thermometer in making a diagnosis of scarlet fever. There is a class of cases in which there is a reversal of the ordinary temperatures noted in scarlet fever, namely, the temperature is higher in the morning and declines towards the evening; whereas one expects to find the reverse in a typical case of the disease. One symptom to which he pins most of his faith is the characteristic angina. As to erythema, there are more variations in this than any single symptom found in the course of the disease. As to desquamation, a few years ago he saw a case in which there was a sloughing off of a cast of the whole upper lip. There was one form of atypical scarlatina which the physician dreaded, namely, scarlatina fulminans, which killed patients by the intensity of the toxins before the physician was able to make a diagnosis. He cited one such case. Dr. Alfred C. Cotton said that in the treatment of scarlet fever the main indications are to support the patient and to aid in the elimination of the toxins. Dr. H. Manning Fish said that one serious ocular complication following scarlet fever is disease of the optic nerve. Dr. William L. Baum said he had searched high and low for a case of Duke's disease during the recent epidemic of scarlet fever, yet he had been unable to find a single instance which tallied with the description of that disease as described by Duke in the London *Lancet*. In all cases of doubt as to diagnosis they relied on examinations of the blood at the Cook County Hospital. Dr. H. B. Hemenway referred to the epidemic of scarlet fever in Evanston. He furnished unmistakable evidence of the epidemic in that city being due to an infected milk supply. Dr. H. W. Cheney spoke of Moser's serum in the treatment of scarlet fever. The effect begins to manifest itself in from eight to twelve hours after injection, and is characterized by a marked fall in the temperature, oftentimes the temperature dropping to normal within twenty-four hours, and continuing there, or nearly so. The pulse shows much the same change. The rash, when the injection of the serum is given early, either does not develop or fades away more rapidly than usual. A most notable change is a marked betterment in the general condition of the patient. The workers in Vienna in the Kinderkrankenhaus are convinced of the value of this serum. One hundred cases have been treated with the serum. Only the severest cases are injected with it. The serum has been used there since 1900. Before that time the mortality from scarlet fever at this hospital was 15 per cent.; since then it has averaged less than 9 per cent. The mortality in other hospitals in Vienna, where the serum was not used during the period since 1900, has averaged 13 per cent. Dr. O. Tydings said the successful treatment of scarlet fever rests principally upon treating the complications which arise during the disease. Dr. H. G. Vaughan referred to an epidemic of scarlet fever in Oak Park, Ill. He thinks that epidemics of the disease can be caused by infected milk. They have had approximately 110 cases of the disease in that suburb, the cases running much the same course as those in Evanston and elsewhere, with suspicion resting upon a company that furnished infected milk. After thorough investigation, however, the members of the Health Department were unable to draw any definite conclusions implicating this milk company. Dr. A. H. Burr of Rogers Park spoke of an epidemic in that city, saying the disease appeared simultaneously with the epidemic in Evanston, and could without doubt be traced to infected milk supplied by one company of milk dealers.

New Instruments.

A NEW X-RAY TABLE.

By M. S. KAKELS, M.D.,

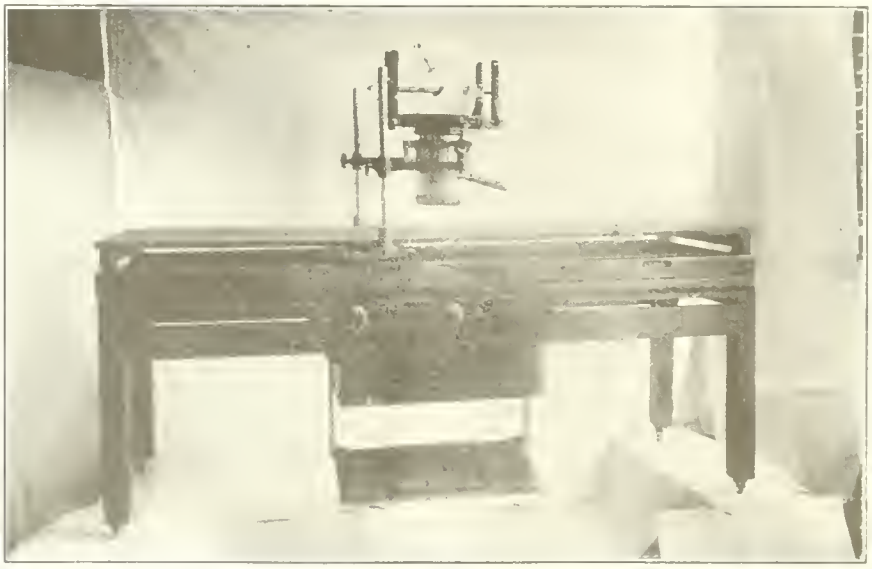
NEW YORK

ADJUNCT SURGEON, LEBANON HOSPITAL

APPRECIATING the desirability of transmitting the x-ray from below through a patient while lying in a horizontal position for fluoroscopy, radiography, or radiotherapy, I have devised for that purpose a table which I present for your inspection this evening.

The practicability of this table overcomes the inconveniences experienced in examining patients who, owing to the nature of their condition, are unable to stand, and in whom it is absolutely necessary either to fluoroscope or radiograph for diagnostic purposes. In surgical practice such cases frequently arise, and the methods heretofore used in examining by the Roentgen ray were impracticable and very limited.

The table is constructed of a strong wooden frame 6 feet 4 inches long by 26 inches wide and 30 inches high. The top consists of two covers. The upper one easily removed is made of wood 1½ inches thick and separated from the lower one by a space of 2½ inches, which is plenty wide enough to admit the compression apparatus, which is fixed on a platform to easily roll from one end to the other,



In its construction, one of the advantages it possesses is that it has combined with it a detachable compression apparatus, which can be readily moved to any position without disturbing the patient, so that any portion of the body may be compressed for radiography or radiotherapy. The other great advantage is a protected Crooks tube carrier, which plays beneath the top of the table, moving either forward, backward, or lengthwise by simply turning the knobs on the side. One can readily appreciate what a distinct advantage this is for the examiner who wishes the aid of the Roentgen ray passing through any part of the body from below.

Of great importance also for the surgeon is this arrangement by which surgical procedures can take place while the tube is in operation without any deleterious influence whatsoever to the operator arising from the ray.

The compression apparatus can thus be easily moved to any position over the whole length of the table while the patient is lying on the top cover without disturbing him in the least, and when not required may be readily rolled off.

*Presented and described before the surgical section of Academy of Medicine, March 1, 1907.

For radiographic work, the movable top has been made of wood, because it offers a firm support when the compression apparatus is employed. The lower cover or top consists of a rectangular frame, over which is tightly stretched a layer of canvas heavy enough to hold a patient of any weight. I have used canvas, as it has practically no resistance to the Roentgen ray. It also has an advantage over fiber wood in that the latter contains impurities and warps in damp weather.

The canvas top is fastened by two hinges to one side of the table, so that, when the upper wooden cover and compression apparatus are removed, it can be easily opened and kept open by stays, for the placing and adjusting the *x*-ray tube in the car which runs underneath it.

The car, containing the Crooks tube, is a wooden box 26 inches long by 14 inches wide and 12 inches deep, large enough to hold an 80 cm. tube. It is lined with a layer of special opaque material and reinforced by a layer of lead glass, which makes a most efficient method for preventing the penetration of the *x*-ray. It is mounted on a truck which moves lengthwise by rack and pinion, while the car itself moves forward and backward on this truck by a cord and pulley arrangement. These movements are controlled and regulated by the two knobs moving with the truck, which extend from the sides of the table. This double movement makes it feasible to center the tube at any spot on the patient while he is lying on the table by simply turning the knobs one way or the other, that is, either to the right or to the left. An opening on the bottom of the box, which is covered by a sheet of lead glass, permits the light to be reflected from a mirror fitted beneath, thus affording the examiner to view the condition of the tube. This mirror is automatically adjusted so that the tube is constantly in sight, no matter where the box may be. The top or cover of the tube-carrying box can be removed for the insertion of a tube of any length. It has a circular opening 4 inches in diameter sufficiently large for admitting the *x*-ray to the part to be examined.

An adjustment on either end of the box consists of a hollow metal tube, containing a spring, which clasps the ends of the Crooks tube, and, besides forming the connecting pieces for the electrical connection to the coil, afford the simplest support for it. When held thus the center of the tube is about 6 inches from the top of the canvas cover. There are many occasions and opportunities which prove the practicability of this table. A patient can easily be carried on a stretcher from his bed, and with it laid directly on the canvas or wooden top for fluoroscopy or radiography. While setting a fracture of the lower extremity, it can be fluoroscoped while the patient is on the table and immediately reexamined and compared with the other healthy limb by simply turning the knobs and rolling the car, holding the Crooks tube under either of them.

I need not dilate upon the immense advantage thus afforded in seeing any errors in malposition and thus facilitating timely correction.

This is but one of the many instances for which this table may be used.

Another practical use for which it may be employed is that by it we have a means for operating in many instances for a foreign body by the Roentgen ray while the operator is absolutely shielded from its influence. Foreign bodies such as bullets, etc., may be located in such parts of the body where on account of the nature of the traumatism inflicted patients are unable to stand.

For practicability it seems to me this table meets all the requirements for which it has been devised. I am indebted to Messrs. Wapper and Bro. for valuable suggestions in the construction of the mechanical parts of the table.

Books Received.

While the Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious disease reported to the Sanitary Bureau, Health Department, New York City, for the week ending March 30, 1907:

	Cases	Deaths
Tuberculosis Pulmonalis	434	221
Diphtheria	311	41
Measles	419	5
Scarlet Fever	379	17
Smallpox	—	—
Varicella	70	—
Typhoid Fever	120	15
Whooping Cough	54	9
Cerebrospinal Meningitis	28	20
Malarial Fever		
Totals	1815	328

Somatic and Psychic Electrotraumata.—Anacleto Romano calls our attention to the manifestations of epilepsy following injuries by currents of low tension and from his studies of the condition concludes that intermittent currents of low tension penetrate the brain and produce a suspension of the functions of the hemisphere; such currents traversing the brain produce epilepsy with the three phases of tonic and clonic convulsions followed by coma. The development of this condition is modified by medication introduced into the circulation as well as by the functional and chemical conditions of the brain. Apoplectiform attacks may also be produced by electric currents interrupted and increasing in intensity. They directly affect the circulation of the brain, or indirectly they paralyze nerves or segments of nerves, such as the vagus. These electrotraumata produce psychical symptoms that are very marked: among others a true form of demential paralytica, preceded by disturbances of the mental faculties. All the neuroses and psychoses may result from electrotrauma. They either predispose to neurotic and psychopathic conditions, or directly determine them. In Vienna has been established a clinic for the treatment of conditions due to the electrical atmosphere and results of the industrial trades in which it is used. The remedies to be used, after an accident by electricity, are such as lower the blood pressure, stimulate the respiration, and quiet the cerebrum. Preventive measures in the line of perfect insulation should be carried out by all companies installing electrical apparatus.—*Annali di Elettricità Medica e Terapia Fisica.*

The Etiology of the Punctiform Hemorrhages in the Mucous Membrane of the Appendix.— Bayer recounts the theoretical and practical considerations which lead him to regard the minute extravasations of blood frequently seen in the mucous membrane of appendices removed during the interval as artefacts produced in the course of the removal of the organ. It is his theory that in tying off the blood supply of the appendix the veins are usually included in the ligature, but the artery often escapes and has to be secured separately later on. In consequence of this there is a tremendous rise in pressure in the capillary network, which results in minute ruptures and hemorrhagic spots. Such lesions may be observed in appendices that have been removed in the most careful manner possible, so that it seems out of the question to consider any mechanical injury responsible for them.—*Centralblatt für Chirurgie.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended March 20, 1907:

TREATMENT OF ACUTE CARDIAC AFFECTIONS IN CHILDHOOD.

By ADOLF BAGINSKY, M.D.,

BERLIN.

EXTRAORDINARY PROFESSOR OF PEDIATRICS IN THE UNIVERSITY OF BERLIN, DIRECTOR OF THE KAISER AND KAISERIN FRIEDRICH HOSPITAL FOR CHILDREN.

The great importance of cardiac diseases in childhood is evident to every practitioner, and under this term must be included not only affections of the pericardium and endocardium, but also those of the myocardium. By the physician engaged in private practice, however, the subject does not always meet with the attention it deserves, because his opportunities for observing the condition must necessarily be limited, his cases being sporadic only. But in the eyes of the hospital physician the disease assumes a much more important and serious aspect, for he meets not only with the acute cases, but also those in which there have been repeated attacks, the patients being brought to the hospital in an almost helpless state with extreme dyspnea, dropsy, and total cardiac insufficiency. Then, notwithstanding an occasional almost phenomenal improvement, the patient will sooner or later succumb to the incurable malady. That at least has been the experience in Germany.

The prevalence of the disease in early years may be indicated by the statistics furnished by the Kaiser and Kaiserin Friedrich Hospital during the administrative year from April 1, 1905, to April 1, 1906. A total of 2,528 children were under treatment in this institution during the period in question, and of these 23, or 0.9 per cent., were admitted for the treatment of acute or chronic cardiac disease. This does not seem like a large number, but we must add 28 cases of acute articular rheumatism, in which without exception the heart was involved, as well as 15 cases of chorea in which there were likewise cardiac complications, so that the total amounts to 66, or 2.6 per cent. And this does not include the cardiac complications occurring as sequelæ of diphtheria or scarlet fever. All in all, we find here an imposing array of cases which, on account of the immediate danger as well as of the possibility of permanent harmful after-effects, merit more serious attention than has been accorded to them. And this is the experience of but one hospital. Variations will undoubtedly occur because the development of articular rheumatism and chorea depends, although probably not so intimately as was formerly believed, to a considerable degree on temperature and climatic variations, humidity, and rainfall. The figures stated may be taken, notwithstanding these exceptions, as a fair average of the proportion of cardiac affections to the other diseases of childhood, if we exclude here the infectious diseases referred to above.

This experience has led me to pay particular attention to the condition under discussion, and as a result a number of papers on polyarthritis, pericarditis, and endocarditis have been published, partly by myself and partly by my assistant, Lachmanski.*

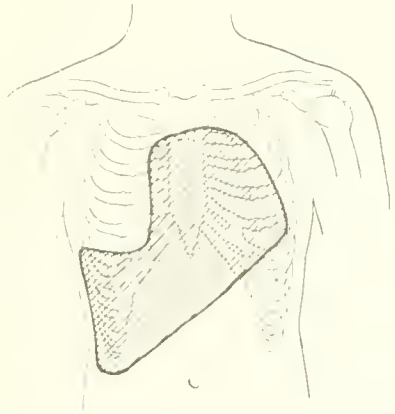

Fig. 1.—Erich Karp; cardiac area, November 28, 1907.

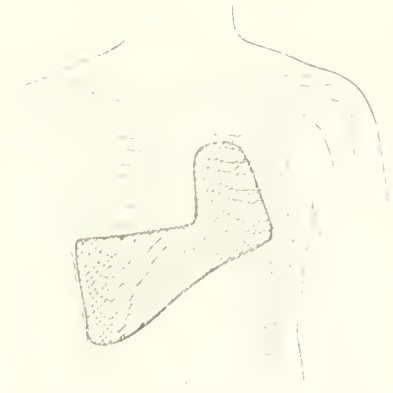

Fig. 2.—Erich Karp; cardiac area, January 8, 1907.

In the present paper I have no intention of taking up the discussion of the extensive field of the therapeutics of cardiac diseases, but will confine myself to a description of the course and the treatment of the acute form of the disease, my remarks being based mainly on a number of noteworthy cases in which pericarditis and endocarditis developed as complicating features of a polyarthritis.

Case I.—Erich Karp, age seven, was admitted to the hospital on November 27, 1906. The boy had pneumonia in early childhood, from which he made a good recovery. When three and a half years of age he had his first attack of articular rheumatism with cardiac complications. About eight days pre-

*Baginsky: *Berliner klinische Wochenschrift*, N. 48, 1898, and No. 49, 1904. Lachmanski: *Archiv für Kinderheilkunde*, Vol. 28, 1900.

vious to admission the boy began to complain of vague pains and headache, and developed a tender swelling of the right knee. There was also pain in the chest and insomnia. Examination at the time of admission showed a pale and poorly developed boy, with considerable dyspnea and occasional marked cyanosis. The right knee was swollen and tender, and the leg was held in a slightly flexed

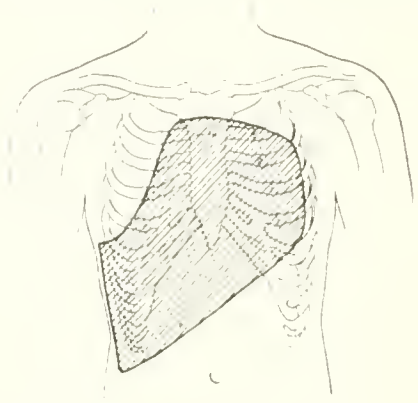

Fig. 3.—Alex. Schledermann, cardiac area, November 29, 1906.

position. The remaining joints were free. Temperature 38° C., pulse 80, regular, with normal tension. The pulmonary percussion note was normal, with the exception of a circumscribed area at the left apex, where it was slightly tympanitic. The respiratory murmur was vesicular, but slightly accelerated. The area of cardiac dullness extended beyond the right edge of the sternum and merged with the upper border of the liver dullness. Above it reached to the level of the second rib and curved down to the left to the anterior axillary line at the sixth rib. The heart sounds could not be distinguished over this area of cardiac dullness, and during the systolic and diastolic periods two loud friction sounds were audible with a maximum intensity over the sternum and at the level of the third and fourth ribs. The apex beat could not be determined. Pulse 100 to 130, regular, not intermittent; temperature 39.5° C. The liver dullness extended about 3 cm. above the costal arch. The area of splenic dullness was not increased. The urine contained a small amount of albumin and a few hyaline and granular casts. The diagnosis was bronchopneumonia, pericarditis with effusion, and nephritis (?). The treatment consisted of an ice bag over the cardiac region with ichthyol ointment and the application of a salicylic acid preparation to the knee joint. Acetylsalicylic acid was given in 0.5 gram doses three times daily. Some improvement took place during the next two days, the pains diminished, and the temperature varied from 37° to 39.5° C. The dyspnea was not marked, but still noteworthy, and the heart action was moderately strong, pulse from 90 to 120. On the other hand, the dullness extended over the lower portions of the thorax in the back to the lower angles of the scapulæ, and there was a diminished respiratory murmur with loss of vocal fremitus.

There seemed to be in addition an increase rather than a diminution in the area of cardiac dullness, and the urine amounted to only 350 to 400 c.c. *pro die*. The acetylsalicylic acid was stopped and soluble digitoxin given internally twice daily in doses of ½ c.c. Inunction with mercurial ointment was also practised, 1 gram three times daily. The ice bag was continued. The boy did not apparently improve much; he continued pale and weak, there was more or less dyspnea, and the temperature varied between 38° and 39.5°, being usually about 39° C. The digitoxin seemed to have little effect on the pulse, which remained around 110 to 120, and of the same general character. On December 1 the digitalis preparation was stopped and potassium iodide solution (3:100) given three to four times daily in teaspoonful doses. On the next day the temperature dropped to 37.25° C. and there occurred a marked change in the general appearance and condition. The dyspnea diminished, although the areas of cardiac and pulmonary dullness were not affected, and the rasping systolic and diastolic murmurs continued unchanged. The euphoria and defervescence continued during the administration of the potassium iodide and the mercurial inunctions, and during the following days the temperature sometimes fell below the normal. By the 10th of December it was possible to make out not only a diminution in the area of cardiac dullness, but also an entire absence of the murmurs. At the apex a blowing endocardial murmur could now be heard. The thoracic dullness behind was also markedly reduced. The urine contained only traces of albumin and isolated casts. The improvement continued, and on January 9 the area of cardiac dullness had reached practically its normal boundaries, and only a weak systolic murmur was heard at the apex. The urine was now free from albumin. The respiratory murmur and percussion note were normal, the pulse was 96 and regular. The boy's general condition was excellent, and he had gained 2.5 kilos in weight. He was dismissed as practically cured with only a remnant of endocardial disturbance.

Case II.—Alex. Schledermann, age thirteen and a half years, was stated to have had a weak heart since his sixth year. The boy was admitted on October 31, 1906, with swollen and painful joints. He was poorly nourished and anemic, weak, and apathetic. The administration of acetylsalicylic acid relieved the pain and swelling of the joints. Then, on the 29th of November, the boy became suddenly feverish, and his appearance indicated collapse. Examination disclosed a marked increase in the area of cardiac dullness, which extended to the second rib above and beyond the right border of the sternum to the extent of 4 cm. At the level of the sixth rib this dullness merged with that from the liver. The apex beat was palpable in the fifth interspace about 2 cm. to the

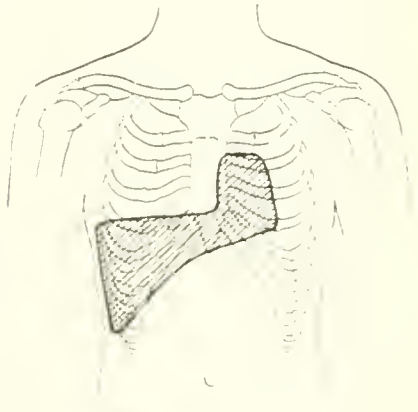

Fig. 4.—Alex. Schledermann, cardiac area, January 7, 1907.

left of the mammary line. A systolic murmur could be heard at the apex and over the mitral area. Over the lower third of the sternum could be detected a post-systolic and diastolic friction sound. There was severe pain over the entire cardiac region; the pulse was 120 to 130, with considerable tension. The urine contained hyaline casts, red blood cells,

leucocytes, and granular epithelium, the total quantity being 800 c.c., with a sp. gr. of 1,015. The liver dullness extended about 4 or 5 cm. above the costal border. Dullness and diminished respiratory murmur were evident over the entire left side of the thorax posteriorly to the angle of the scapula. A teaspoonful of potassium iodide solution (3:100) was given every three hours and inunctions with 1 gram of mercurial ointment three times daily. The patient's general condition did not undergo any appreciable change during the next few days. He remained very pale and seemed exhausted. In addition to the other medication he was then given ½ c.c. of the digitalis preparation used in the former case three times daily, which gradually effected a diminution in the frequency of the pulse rate (100 to 110). Iron was also administered, and after a time, with the treatment noted, the more serious symptoms subsided, and the condition of apathy and collapse disappeared. By December 18 the area of cardiac dullness had undergone considerable diminution, particularly on the right side, and at the apex a saw-like murmur could still be heard. At the base a systolic murmur was evident and the second pulmonary sound remained accentuated. The improvement from now on was rapid, the cardiac dullness as well as that over the posterior aspect of the thorax gradually subsiding. On December 29 the boy, who had become bright and cheerful, was allowed to leave his bed. The apex murmur could still be plainly heard. On January 9 the patient was dismissed as practically cured, with the evidences of a slight mitral insufficiency and an area of cardiac dullness about normal in extent. There were adhesions present in all probability between the heart and the pericardium, as shown by the physical signs obtained on changing the position of the patient.

These two cases are not, of course, particularly noteworthy, and agree in their main features with those of articular rheumatism complicated by acute cardiac lesions. Their instructive character is dependent entirely upon the therapeutic aspects.

In the first case the pericarditis dominated the clinical picture. The friction sounds showed that in addition to an exudate we had to deal with the formation of adhesions between the heart and pericardium. The administration of acetylsalicylic acid seemed effective in controlling the polyarthritis, but was entirely without effect on the endo- and pericarditis. The application of an ice bag, although agreeable enough to the patient, seemed to have as little effect in reducing the inflammatory symptoms as the ichthyol ointment or digitalis. The patient in fact was placed in mortal danger by the dyspnea and the threatened cardiac collapse. A certain and rapid improvement did not take place until the combined administration of mercurial inunctions, and potassium iodide was instituted. This is a combination which was formerly rather in disfavor, and even feared on account of its possible chemical incompatibility, but has been shown by actual experience to be perfectly harmless in its application. Of all the remedies which I have hitherto employed in the treatment of acute inflammatory diseases of the heart, the pericardium, the pleura, and even of the lungs, I am compelled to acknowledge potassium iodide as the most efficient. Its effects in pericarditis seem to be increased by the combination with mercurial ointment, and in the condition of complete helplessness which the practitioner is often compelled to acknowledge in the presence of the rheumatic cardiac diseases, this method of treatment may safely be commended. The endocarditis which manifests itself in these cases by very stormy symptoms may be effectively combated by the ice bag and the internal administration of digitalis. Of course these methods are only of value in overcoming the immediate danger, and thus far I cannot say with certainty whether they are able to prevent the production of a chronic endocarditis or chronic valvular disease.

The second case has led practically to the same results as the first. Here we had to deal with inherent cardiac weakness, to which there was added during a recurrent attack of polyarthritis an endocarditis and pericarditis. Although mild at first, the pericarditis, with an effusion added to that from the pleura, constituted a serious menace to the life of a boy already in a very weakened condition. In this instance also the combined use of mercury and potassium iodide showed itself a most efficient remedy. The administration of digitalis was indicated by the endocardial condition, and its efficacy appeared to be undoubted. The action of the potassium iodide is worthy of particular attention, for the surprisingly rapid absorption of the serous exudates can hardly be regarded as spontaneous, and must in all probability be attributed to the effect of the iodide.

There are two questions which must be considered in regard to this subject. (1) Should any resort be had to venesection at the height of the disease in these cases; and (2) Is early puncture with the needle indicated where an extreme degree of pericardial effusion is present? Venesection, formerly in great favor but later abandoned, has recently been revived by some English authors as a therapeutic procedure. I have used the method in two cases, one of acute endocarditis complicated with pericarditis, the other of acute cardiac dilatation with violent heart action, with some success as regards the pain and overactivity. The disease itself did not seem to be in any way affected, and the pain and dyspnea returned. The second case ended fatally. On account of this experience I feel that I can scarcely recommend the abstraction of blood in these cardiac cases as a safe or efficient procedure, for, aside from the difficulty of controlling subsequent hemorrhage, there is also the danger of septic infection from the wound caused by the leech bite.

Exploratory puncture of the pericardial sac is undoubtedly indicated in certain cases where the diagnosis of a large pericardial effusion can be made with accuracy. This, however, is sometimes a very difficult matter, particularly in children, where the condition may be confused with acute cardiac dilatation. When the dyspnea is extreme, the pulse small, frequent, and irregular, the value of aspiration is undoubted. In the second one of our cases I would certainly have resorted to this procedure if the exudate had not been so quickly absorbed under the influence of the potassium iodide. In those cases where the pericardial exudate is combined with an even larger one of the pleural cavity, it is advisable to combat the dyspnea by doing a paracentesis of the chest before that of the pericardium is attempted. It will often be found that the dyspnea disappears, and then puncture of the pericardium is rendered unnecessary.

Another remedy which has lately been revived by the French writers is the application of vesicants over the cardiac area. I do not desire to recommend this procedure, which is not only cruelly annoying and distressing for children, but is inefficient. There is also a danger to life in using this method, for the wounds caused may become the site of a diphtheritic infection, as has been shown in a

number of instances. The suggestion should therefore be abandoned.

Both of our patients showed evidences of renal irritation—albumin, blood, and casts in the urine. A proper degree of diuresis should therefore be provided for, which may be accomplished by the administration of the alkaline mineral waters without the use of stronger diuretic measures. The latter may be reserved for certain extreme cases. Cases of chronic heart disease furnish entirely different indications and demand the application of cardiac tonics (digitalis, caffeine, strophanthus, valerian) in combination with diuretics. I have included only those acute conditions in which the pericarditis occupied the foreground of the clinical picture, and shall discuss the chronic cardiac diseases of children at another time.

LOCAL THERMOTHERAPY.*

By W. GILMAN THOMPSON, M.D.,

NEW YORK.

THE topical application of heat and cold in the treatment of disease processes is one of the oldest known therapeutic measures, but owing to the progress of physiology, pathology, and the surgery of localized pyogenic inflammations, there has been, of recent years considerable modification of the views regarding its efficiency. Thus it may be stated in general that while the development of peripheral local thermotherapy has been greatly advanced by improved technique in combined methods of douching with massage and by the so-called "baking" processes, etc., there is, on the other hand, increasing scepticism as to the possibility of modifying deep-seated visceral congestions, inflammations, or hemorrhages by means of any external local thermic applications. Is there any use in attempting to control the hemorrhage of typhoid fever by an abdominal cold coil, to control pulmonary hemorrhage by an ice bag, to modify the course of a pneumonia by poultices or cold compresses, or the course of appendicitis, or an otitis media, or a quinsy, by the laying on of cold? Can the function of the kidneys be stimulated by lumbar poultices, or the course of meningitis be influenced by an ice cap at the head or neck? Is there any real value in any of these measures other than the fact that they sometimes, though by no means invariably, contribute to the comfort of the patient. And if, on the contrary, they annoy him, should their use be nevertheless continued? Being unable to find any satisfactory experiments determining the penetrating power of heat and cold locally applied to the surface of the body, I undertook such a series of experiments upon animals some years ago while working in a physiological laboratory. I have never published them in full, as they were made primarily for my own guidance, but I have supplemented them from time to time by further researches upon the human body, and believe that they possess considerable interest as well as practical importance in connection with the present discussion.

In conducting the experiments I used special thermometers, similar to those employed in thermostats, and used also by beer brewers. These thermometers are about ten inches long, with slender stems and small bulbs, a little larger than those of the ordinary clinical thermometer. They possess a wide range of index, and are not self-registering, so that fluctuations alternating both above and below the normal body temperature are promptly observable. As the bulbs are small, they are quickly influenced, and as the stems are long they may be deeply inserted into cavities in an animal or the human body. In experimenting with poultices three thermometers were simultaneously used, one inserted in the poultice itself, one placed between the poultice and the skin, and one in some cavity of the body immediately beneath the poultice. In anesthetized animals, punctures were made into various cavities of the body, and thermometers inserted at various depths beneath the site of application of the poultice. In the living human subject thermometers were inserted in the buccal cavity, in the bladder, in the rectum high up, and deeply into the thorax in several cases of post-operative empyema with long sinuses. In the human cadaver punctures were made in the abdominal wall and thorax, and thermometers inserted and held against the inner surface of the wall, while poultices, ice bags, ice, coils, etc., were applied in alternation immediately external to the thermometer bulbs. The results were in all cases most striking, and proved that so long as the normal peripheral circulation is maintained, neither extremes of local heat or cold possess penetrating power of any practical importance whatsoever. In other words, the thin layer of blood in the cutaneous or subcutaneous circulation passes along with such rapidity as to constantly remove any thermal units, so to speak, and prevent deeper penetration. As soon as an animal is killed, however, and the circulation ceases, or if the experiment be tried upon the human cadaver, extremes of both heat and cold acquire considerable penetrating effect. So promptly does the peripheral circulation act in dissipating or neutralizing external local heat or cold that the thermometer placed between the skin and the poultice or ice bag shows much less change than might be expected. (In all the experiments herein recorded the Fahrenheit scale was employed.) A poultice made by adding boiling water to flaxseed meal usually cools down to about 140°-145° before it can be applied to the patient. If the mixing bowl be previously heated, and the meal itself be warmed, a poultice can be made as hot as 160° or 165° or more. Patients vary much in their ability to tolerate external local heat, and there is, moreover, much difference on the various parts of the body. Usually a hotter poultice can be borne over the face than elsewhere, and here a temperature of 150° may be endured, but most persons find a heat much above 140° uncomfortable, and some cannot endure more than 125° or 130° on the thorax. Poultices made of Indian meal or boiled mashed potatoes retain their heat somewhat longer than flaxseed. As ordinarily applied by trained nurses, a flaxseed poultice loses about 20° of heat in the first half hour, starting at 140°, and the other varieties mentioned lose about 15°. The addition of sweet oil keeps the poultice pliable, but does not materially affect its heat radiation. The ice water coils, which are referred to in these experiments, were made with about 11 feet of rubber tubing fed from a pail of iced water. After running through such a tube, the water temperature is usually about 38°. A thermometer placed between the skin and the coiled rubber tubing registers on an average 58°, or between the skin and poultice 105.5°. At the normal body temperature the total heat units contained in a human being weighing 140 pounds, would be nearly 14,000 as compared with those of a flaxseed poultice weighing one pound at 140°, which would contain only 140 units. Hence, the total heat of the poultice is inappreciable compared with that of the human body.

* A paper read before the Practitioners' Society, March 1, 1907.

In an anesthetized dog a thermometer was pushed into the lung and a poultice at 146° was placed over it on the outer surface of the shaved chest wall. At the end of 25 minutes no effect whatever was produced on the internal temperature. In another animal a hotter poultice at 160° was applied, but the lung temperature was raised only 0.6°. When an ice water coil was substituted for the poultice, the lung temperature was made to fall 1.8° in 25 minutes. When the dogs were killed, however, the lung temperature was made to rise 5° with the poultice, and to fall 15° with the coil. Similar results were obtained by placing the thermometer within a dog's abdomen and making thermic applications over it on the outside. In all the experiments of this nature it will be observed that the topical application of cold produced a relatively greater effect than that of heat. This is doubtless due to the fact that the source of heat, the poultice, is steadily and rapidly cooling off, whereas the source of cold, the ice water, remains constant. These experiments were made in 1890 before the days of the electric heating pads, now so commonly used, in which the source of heat supply remains a constant quantity.

Prolonged ether inhalation is apt to lower the general body temperature in dogs. In one animal, after an hour's continuous ether inhalation, the intraabdominal temperature fell from 101° to 97°. A poultice at 150° was then applied over the thin abdominal wall (which was not more than 1-3 inch thick). A thermometer inserted in the abdomen and pressed close beneath the poultice showed a rise of 5.5° F. in temperature, but held one-half inch deeper, *i.e.* away from the abdominal wall, it only recorded an elevation of one degree. The intestinal capillaries were carefully studied during the experiments, but neither very hot poultices (150°) or very cold coils produced the slightest appreciable effect upon their color or caliber. A single exception occurred in the case of a dog with a very thin abdominal wall. The hair was shaved over the abdomen, and, after application of a poultice at 168°, considerable congestion was apparent in a coil of intestine immediately beneath the poultice. This degree of temperature, however, could not be endured by man, and could only be tolerated by a dog when anesthetized. In the same animal prolonged application of an ice-water coil produced no visible effect on the intestine.

In an anesthetized dog a portion of the trachea was exposed to view, while, in alternation, poultices and ice bags were applied over the animal's neck and also over the thorax, but there was no visible evidence of either congestion or of blanching of the capillaries of the tracheal mucosa.

In another anesthetized dog a small glass window was inserted in the thorax in an aperture made by excising a portion of two ribs. The window was made with a double flange, which held it in place, when the skin was hermetically closed around it. The air which entered the pleural cavity was aspirated out, and the lung then expanded against the window. The dog's lung is of a delicate pink color, easily showing variations in tint depending upon fluctuations in blood supply. Through the glass window it was possible to observe the lung under practically normal respiratory conditions while hot poultices and ice coils were applied in alternation to the overlying thoracic surface. No changes of any kind were perceptible in the appearance of the lung, even when rapid alternation in extremes of external temperature were made, or when a poultice was placed on one side of the chest and an ice coil on the other. Variations in the rate of breathing were sometimes observed, due to the reflex stimulation induced by sudden changes in temperature. The color of the lung surface was considerably modified, however, by varying the quantity of ether inhaled. These experiments were repeated upon several animals with uniform results, and they make it difficult to believe that cold applications to the thorax can ever materially influence pulmonary hemorrhage.

To determine the transmission of heat through the cheek, as when a poultice is applied over an inflamed gum, the following experiments were made:

I.—Temperature inside of cheek, 97°. A poultice at 152° was applied for 15 minutes, when the temperature of the inner surface of the cheek rose 1.7°.

II.—Temperature inside the cheek, 97.8°. Poultice at 160° applied 15 minutes; internal temperature rose 0.6°. During both these experiments the temperature of the poultice fell 30° in 15 minutes, although it was well protected by towels.

III.—Temperature inside the cheek, 98.6°. Poultice at 150° applied for half an hour; temperature rose in mouth 0.5°. A thermometer placed between the poultice and the outer surface of the cheek recorded only 105.6°, although the thermometer in the center of the poultice registered 150°. The gum appeared slightly reddened beneath the poultice on the affected side. A poultice at 160° applied on the outside of the neck for some minutes produced no appreciable effect upon the color of the mucous membranes of the larynx or pharynx, but when ice was applied directly afterwards, decided pallor of the mucosa of the posterior pharyngeal wall and base of the uvula was apparent. An immediate reapplication of the poultice produced no further change, the mucous membrane remaining pale for a considerable period.

In a patient having a deep, straight empyema sinus, I was enabled to insert a thermometer bulb eight and a half inches into the thorax. The thermometer registered 99.8°. After 15 minutes' application of a poultice of 140° over the adjacent thoracic wall, the lung temperature rose only 0.4°. An ice poultice, made of pounded ice mixed with flaxseed meal to prevent too rapid melting, was then applied. After 15 minutes the lung temperature was absolutely unaffected.

In a second case of post-operative empyema, a thermometer was inserted through the sinus one and a half inches into the thorax. A poultice at 144° applied externally raised the temperature only 0.6° after 20 minutes.

Several years ago I happened to have three women patients in hospital, who for various reasons had worn large cold coils over the abdomen and pelvis for several days almost continuously. Each one developed a marked cystitis, although neither one had been catheterized or had gonorrhea. I was led to wonder whether this occurrence was a mere coincidence or whether the cold had in any manner reduced the resisting power of the bladder. I therefore inserted thermometers in the bladders of several female patients and applied externally both poultices and ice coils *seriatim*. In one case an hour's application of the coil over the pelvis reduced the internal bladder temperature only 0.6°. In a second case there was a variation of only 0.2°, which, moreover, proved to be wholly independent of all external applications. It does not seem possible, therefore, to directly transmit either heat or cold to the bladder by the means above mentioned. In the bladder there is not alone the circulation in the vesical wall, but the constant entrance of warm

urine to be reckoned with as factors in neutralizing external local thermic applications.

In seven women who were given vaginal douches at a temperature of 114° to 116° the maximum rectal temperature was 3° higher immediately after the douche than before, but the average elevation was only 1.6°, showing that even as thin a layer of tissues as the rectovaginal wall suffices, owing to its high degree of vascularity, to prevent local heat accumulation in any marked degree.

The question to what extent the heart may be influenced by local external thermic applications is of considerable importance. If a neurotic patient with palpitation be told to place an ice bag almost anywhere on the body and lie down and keep quiet, the heart action will be slowed, and it is not well to attribute too much importance to the ice bag, which may have a purely psychic effect. There are cases, however, of true angina pectoris in which the pain is mitigated by placing a hot poultice over the precordium, and there are cases of tachycardia and of pericarditis in which undoubted relief, both of pain and rapid heart action, seems to be produced by the continued application of cold to the precordium, but there are also many cases of tachycardia in which cold seems to produce no effect. If such applications prove of use clinically, they are certainly harmless, and are desirable, no matter what may be the theory of their mode of action. It is nevertheless interesting to speculate upon this matter, and it is not my belief that local heat or cold is ever made to reach the heart, or even pericardium directly, but only to exert indirect reflex nerve excitation or inhibition through the cutaneous nerves.

Experiments were made to determine to what extent the stomach is chilled by drinking ice water. In one patient who swallowed a tumblerful of iced water at 37°, the water, after being recovered with a stomach tube in 5 minutes, was found to have a temperature of 76°. In another patient water at 36° was allowed to remain in the stomach for 10 minutes, when, upon withdrawal by syphonage, the temperature registered 90°. In a third case water swallowed at 35° was recovered in 2½ minutes at 70°.

In marked contrast with the failure to modify the deep internal temperature of organs in the living body are the results of the same topical applications to the cadaver. A thermometer was inserted beneath the abdominal wall in a cadaver, and a poultice applied externally over it. Although the poultice used was not very hot—only 114°—within half an hour the intraabdominal thermometer showed a rise of 14°. When a cold coil was applied under similar conditions, using water at 36.5°, the intraabdominal temperature fell 15° in the same period, and continued falling for some time thereafter. No other result would of course be expected, but it is instructive to note the relatively rapid rate of heat transmission through dead tissues in distinction from the living.

The chief interest of these experiments concerns the common employment of topical cold for supposed influence in arresting deep internal hemorrhage, from the lungs, the stomach, or the intestine, as in typhoid fever. Clinically, I have never been convinced that the use of ice bags, ice poultices made with flaxseed, cold wet compresses, ice coils, etc., was of any value whatever, beyond the fact that they may be somewhat soothing to the surface, and to balance them in position the patient must lie quiet upon the back. Rest, and possibly the morphine commonly given in such cases, are the real factors, and from experimental observation I am convinced that topical applications of cold can never modify the caliber of deep-seated vessels sufficiently to exert any astringent effect. In the great majority of these cases the hemorrhage ceases spontaneously when the blood pressure falls sufficiently low, or the blood stream is retarded. Theoretically, the depletion of peripheral blood-vessels by cold would tend to raise internal blood pressure, and thus favor the hemorrhage, but practically this also is an insignificant factor. Similarly the swallowing of cracked ice, for control of hemoptysis or hematemesis is useless, for the ice is melted in the mouth, and the ice water, in its slow passage through the esophagus, is warmed by the blood-vessels long before it reaches the stomach. It may serve to allay somewhat the patient's anxiety if he shares the popular faith in its efficacy, but it is without scientific reason. In situations where heat can be directly applied to the bleeding surface, as, for example, the nasal mucosa, it is well known that to produce any astringent effect a temperature of at least 110° or 112° must be employed, lesser degrees of heat tending to favor continuance of the bleeding. Similarly, to successfully control oozing of blood from the surface of the skin or mucous membranes, moderate degrees of cold are of little value, but ice itself must be employed.

In all the foregoing experiments it has been shown that a deviation of onehalf to one degree from the normal is all that can be obtained under most favorable conditions, when deep-seated vessels are expected to be influenced by external local thermotherapy. Such trifling temperature reactions cannot be believed to influence the caliber of capillaries, or the coagulation of blood. Hemorrhage from the uterus presents of course an entirely different proposition, for the hemostatic effect of hot water or of ice within this organ depends chiefly on the stimulation to the uterine muscle to contract.

With regard to the common practice of poulticing the lumbar region to relieve congestion of the kidneys and favor diuresis, it may be similarly argued that these organs lie too remote from the surface to be affected by any degree of heat penetration. Clinically, I have never seen results from such treatment which were not to be traced to some other factor.

As regards pneumonia, the articles claiming "cures" by either continued poulticing or local refrigeration, which were so common in medical literature fifteen or twenty years ago, have well nigh ceased to appear altogether, doubtless owing to a broader conception of the pathology of the disease. In cases with severe pleuritic pain, they unquestionably often give much relief to the patient, and in such cases their use is desirable. Although they possess some reflex effect in alleviation of pain, they are absolutely without influence in modifying the course of the disease.

The use of heat or cold to accelerate or abort deep-seated pus formation is now generally regarded as of much less importance than formerly. An ice bag may relieve the pain of appendicitis, and aid in quieting the patient, but it is not to be regarded as a factor worthy of any consideration in checking a suppurative process, and to make use of it to temporize, may prove highly dangerous for the patient. The same is to be said of the former practice of applying poultices to draw deep-seated pus to an outward focus, while the patient is becoming daily more septic.

In depreciating the value of topical thermotherapy for deep-seated hemorrhages, congestions and inflammations, it is by no means intended to reflect

upon the value of such treatment for the relief of visceral pains. To do so would be to oppose universal experience. Most certainly the pain of pleurisy is relieved by local hot or cold applications, as the case may be, just as gastralgia and enteralgia and the various abdominal colics are relieved and often cured by a poultice or hot water bag. But such relief is quite apart from any question of vasomotor influences, through direct caloric transmission, and is explainable rather upon the obscure reflex relationship between the cutaneous nerves and the nerves of the viscera most nearly related to them topographically.

I have stated that while the modern view of local thermotherapy tends to lessen its importance in the treatment of certain deep-seated visceral diseases and disorders, it is rapidly gaining importance in the treatment of peripheral lesions. Here the conditions are altogether different, for not only may the cutaneous sensory nerves be affected, but the underlying vasomotor nerves, the caliber of the vessels, the local temperature of the blood, the sweat glands, and the muscles and ligaments, are all within the immediate reach of direct thermic influences, which are known to modify local innervation, nutrition, and functional activity to a phenomenal degree. Moreover, this peripheral treatment is greatly reinforced by such adjuncts as local massage and the mechanical stimulus of pressure, as when the alternating hot and cold douche is given with scientifically adjusted force and combined with mechanical manipulations.

It is a matter of astonishment and regret that so few of our large general hospitals have thus far made any provision for methods of treatment, which are proving of increasing usefulness as they are better understood. In many a hospital in this city the sole bathing outfit for a large general ward consists of a small tub placed against the wall, usually in a water-closet—an arrangement as inadequate as it is unhygienic and unesthetic! A very large class of patients can receive no satisfactory treatment in the general hospital ward, such as cases of chronic and subacute rheumatism, arthritis deformans, local neuritis, chronic gout, gonorrheal arthritis, a variety of muscular atrophies and dystrophies, sciatica, lumbago, neuralgias, hemiplegias, besides a variety of surgical injuries, etc., because what they really need is not to be put to bed and given potassium iodide, but a thorough course of local thermotherapy combined with or rather including hydrotherapy, massage, and other manipulations, together with good fresh air and all-round hygiene. The strongest stimulation of peripheral nerves is often best obtained through the rapid alternation of extremes of temperature, combined with mechanical shock such as that communicated by a stream of water under carefully graded pressure. To accomplish such treatment special apparatus is needed wherewith the temperature of the water used may be rapidly changed and accurately measured, at the same time that the douche stream may be modified in form, as well as in force.

No modern foreign general hospital is now regarded as complete without a large establishment comprising a series of rooms fitted with every kind of apparatus for douching under modified pressures and temperatures, applying local and general hot-air baths, electric light baths, steaming, local sand baths, massage, and vibration, etc., all under the manipulation of well-trained attendants. Anyone who is familiar with the results which such methods are capable of yielding cannot but regret that our own facilities in this direction are so meager.

In conclusion it may be stated:

1. That the topical application of thermotherapy is of little if any value in controlling deep-seated visceral hemorrhages, congestions, or inflammations.

2. That experiments demonstrate that the ordinary means of applying local heat and cold to the surface completely fail to affect the temperature of structures lying beneath the skin to any practical extent, so long as the peripheral circulation remains active.

3. That thermotherapy as applied to the peripheral structures of the body is of so much importance that more adequate facilities should be provided for its employment.

34 East Thirty-first Street.

ANEURYSM OF THE ARCH OF THE AORTA

WHICH RUPTURED INTO THE ESOPHAGUS IN A YOUNG WOMAN WITHOUT EXTERNAL EVIDENCE OF SYPHILIS.*

By GEORGE L. PEABODY, M.D.,

NEW YORK

The aorta and adjacent viscera, which I present to you this evening, are chiefly of interest as throwing light on a somewhat obscure question of diagnosis, and also as suggesting caution in the use of the stomach tube in cases of dysphagia.

The patient was a healthy-looking woman, thirty-three years of age, who appeared much younger. She came under observation early in January of the present year, and died just eleven days later. She told us that her father had died at the age of 48 of some unknown disease, and that her mother had died at the age of 35 of cancer of the rectum. She knew of no other disease in the family. Although always of nervous temperament herself she had never been ill since she had measles in early childhood; she had never suffered from heart symptoms, and had never had any manifestations of syphilis. She had borne several healthy children, who were alive and well, and had had no abortions or miscarriages. She was accustomed to drinking four or five cups of coffee a day and two or three glasses of beer before retiring at night.

Five weeks before admission she had first noticed a feeling as if her food was arrested in its passage to the stomach at the level of the ensiform cartilage. This seemed to cause a sharp, stabbing pain at this point, which radiated to either side in what she called a "band-like" manner, circling the body, and meeting behind in the lower dorsal region. There, at times, she experienced a sensation as of a severe burning, which passed through the body like a knife to the starting point of all her pain underneath the ensiform cartilage. This pain had become almost constant and interfered with sleep. To gain relief she had become accustomed to taking morphine. Associated with this was a well-described globus hystericus. Her physician—a man of experience—had first passed a stomach-tube two weeks previously, and had, he thought, encountered a slight obstruction ten inches from the teeth, beyond which the tube had readily passed. The stomach was always found empty. The passage of the tube was not painful, but it had given her no relief.

One week before admission she thought that solid food was more difficult for her to swallow than fluid. Occasionally the withdrawal of the tube had

*Presented at a meeting of the Practitioners' Society of New York, Friday, March 1, 1907.

been followed by a little bloody mucus—not more than frequently follows its use in gastric cases. Of late the dysphagia had been less marked and less constant, and all of her symptoms had been improving.

She was a little hoarse, and very nervous and anxious, and, although well nourished, said she had lost twenty-five pounds in weight. Her conjunctival reflexes were absent and her pharynx entirely anesthetic to palpation. Her pupils, heart, superficial arteries, and radial pulses were normal, as were also her lungs. Percussion and auscultation of the chest revealed nothing abnormal.

There were no scars upon the surface of the body and there were no enlarged lymphatics. Thus, it will be observed, there were present many of the typical stigmata of hysteria, and there was a complete absence of all the physical signs of thoracic aneurysm, together with both of the etiological factors that go to justify that diagnosis. Her age and sex, too, were factors rather in favor of hysteria than of aneurysm, and when you add the well-described globus hystericus, and the corneal and pharyngeal anesthesia, I feel that an error in diagnosis is at least explained, if not justified.

For a few days she was put upon milk diet, cold pack, faradism in site of pain, laxatives, and sedatives at night.

She continued to complain of pain, to vomit, and to have the same and an increasing difficulty in swallowing.

Lavage showed a slight amount of mucus in the stomach-washings—nothing more. Occasionally a little bloody mucus adhered to the tube on its withdrawal. For some days she was fed once daily through the stomach tube. The passing of the tube was not difficult, although about ten inches from the teeth it always encountered some resistance.

She slept badly on account of the pain, and continued to lose weight, and as her symptoms did not yield to the usual methods of treating hysterical dysphagia, it was deemed wise to have an *x*-ray photograph of her thorax, the negative of which I show you here. This established the diagnosis of aneurysm of the descending aortic arch and showed clearly its displacement of the esophagus. Before the photograph was taken the patient swallowed some bismuth subnitrate, whose presence demonstrates in the photograph the distention of the esophagus above the site of its constriction by pressure of the aneurysm.

Rectal feeding was then resorted to. Naturally she continued to do badly. In a few days more she suddenly vomited about ten ounces of blood and became pulseless and cyanotic, and in a few minutes died.

The autopsy showed a small, false aneurysm of the descending aortic arch which communicated with the esophagus through a large, ragged opening. Her stomach was full of blood. In the arch of the aorta were several raised patches of that kind of aortititis without calcareous change which is commonly re-

garded as of syphilitic origin. Sections taken from these patches, as well as from the wall of the aneurysm, show the areas of atrophy of elastic fibers, which are also regarded as diagnostic of syphilis.

The specimen in gross I will demonstrate to the Society, and will also show the sections under the microscope to those who are interested in looking at them.

DIAGNOSIS OF EARLY PREGNANCY WITH REFERENCE TO A PARTICULAR SIGN.*

By LOUIS J. LADINSKI, A.B., M.D.,

NEW YORK.

ADJUNCT PROFESSOR OF GYNECOLOGY, N. Y. POLYCLINIC MEDICAL SCHOOL AND HOSPITAL; VISITING GYNECOLOGIST, BETH ISRAEL HOSPITAL; VISITING SURGEON, GOUVERNEUR HOSPITAL; CONSULTING GYNECOLOGIST, JEWISH HOSPITAL FOR DEFORMITIES AND JOINT DISEASES.

THE fact that the question of pregnancy sooner or later solves itself is probably one of the main reasons for the comparatively little attention that has been given to the study of the signs of early pregnancy.

Not only are there innumerable instances where it is extremely desirable that a diagnosis of early pregnancy be made, either in the interest of the patients or as a test of the diagnostic skill of the physician; but the knowledge of the presence or absence of pregnancy is often of the greatest importance to the life of the patient from a medical and surgical standpoint.

As a material aid in differential diagnosis it is of especial value in a number of very important gynecological conditions, among which may be mentioned: Extrauterine pregnancy; tumors, including myomata and hematometra, inflammatory conditions of the uterus; cysts of the ovaries and tubes; ovarian cysts complicating pregnancy; and spurious pregnancy.

The teaching on this subject, as expressed in the best text-books on obstetrics and gynecology of the present day, are in my opinion misleading and erroneous, as, for example, Williams in his book on Obstetrics makes the following assertion (p. 157): "Mistakes in diagnosis are most frequently made in the first months of pregnancy": and again he says: "It is often a matter of considerable importance that a diagnosis be made in the early months of pregnancy, but unfortunately it is just at this point that our diagnostic ability is most restricted." On page 119 of Edgar's book is the following statement: "A number of symptoms and signs taken together give certain evidence of the presence of pregnancy; and single signs, especially in the latter part of pregnancy, render the diagnosis probable or even positive."

My observations in this field, extending over a period of about fifteen years, and based on verified results obtained from the examination of a very large number of patients in dispensaries and clinics and in private practice, are entirely at variance with the above doctrine, which represents the generally accepted views of the present day. My experience has convinced me, and this opinion is shared in by my clinical associates, that a diagnosis of "early uterine pregnancy" can be made or excluded in nearly every instance with almost absolute certainty.

The textbooks give the following classification of the signs and symptoms of early pregnancy: They are divided into: (1) Presumptive; (2) probable; (3) positive.

The presumptive signs are mainly subjective, and are to be considered in the early months of pregnancy. They consist of: (1) Amenorrhea, (2) changes in the breast, (3) morning sickness, (4) urinary disturbances, (5) discoloration of the vagina.

The probable signs refer also to the early months of pregnancy, when the following can be obtained:

FIG. 1.—Position of the two hands in the bimanual examination for the diagnosis of pregnancy (Edgar); Hegar's sign is obtained by pressing the external hand deep down into the abdomen and grasping the lower uterine segment between the two hands.

(1) Changes in the shape and consistency of the body of uterus, (2) changes in the cervix, (3) increase in size of uterus, (4) intermittent contractions of uterus.

The positive signs are: (1) Fetal heart beat, (2) passive and active movement of the fetus, (3) outline of the fetus.

From this classification it will be noticed that the signs given as positive refer entirely to the fetus, and are to be looked for only in advanced pregnancy, and do not therefore apply to the period under discussion.

Of the presumptive signs the changes in the breast and discoloration of the vagina do not, as a rule, appear in the early months of pregnancy, and we must depend on the patients for the other presumptive symptoms, namely, morning sickness, urinary disturbances, and amenorrhea.

Morning sickness may occur at the beginning of the fifth week, and last several or more months, but

*Read at a meeting of the Section of Obstetrics and Gynecology of the New York Academy of Medicine, February 28, 1907.

it is found only, according to various observers, in from 15 to 50 per cent. of cases of pregnancy, and it may also be the result of nervousness, anxiety to conceive, or fear of an illegitimate pregnancy.

Bladder symptoms are so unreliable as to be absolutely valueless.

As for amenorrhea, we know that pregnancy may take place during an interval of the cessation of menstruation as the result of other diseases, or because of lactation. Frequently a false history of amenorrhea is given by patients who purposely wish to deceive the physician, and occasionally a period may be missed because of fear of conception; and there are cases on record of menstruation during the first months of pregnancy.

The signs therefore of pregnancy in the early months, and these are considered only as probable signs, are: (1) Changes in the shape and consistency of the body of the uterus, (2) increase in size of uterus, (3) changes in the cervix, (4) intermittent contractions of uterus. Of these signs the last two, namely, changes in the cervix and intermittent contractions of the uterus, can be looked upon only as corroborative signs.

Fig. 2.—Position of the two hands in the bimanual palpation of the uterus for the detection of the elastic area of pregnancy; the external hand used only for counter pressure; the arrow indicating the site of the elastic area in the 5th or 6th week of pregnancy.

I have found, however, that the change in the consistency of the uterus is an invariably constant and positive sign of early pregnancy; and furthermore that this change can be detected frequently as early as the fifth week, but always in the sixth week of pregnancy. As an indication of pregnancy it is in my opinion equally as reliable as any of the positive signs of advanced pregnancy.

Numerous observers have noticed a peculiar change in the consistency of the uterus in the early months of pregnancy, and have offered it as an important indication of pregnancy, but in their descriptions and interpretations of the changes observed they have differed materially from one another. As, for instance:

Von Braun describes the change to consist of "a more or less longitudinal furrow, dividing the uterus into two halves, one of which, usually the left, is softer than the other." Landau finds compressible points at the uterine cornua. Lohlein and Gardner call the changes "A cystic softening of the uterus." Dickinson considers "A bellying or bulging of the fundus and elasticity of the body of the uterus" as pathognomonic of pregnancy.

Hegar's sign was first described by Rheinl, in 1884, and is obtained by bimanual palpation, with one hand upon the abdomen and one or two fingers in the vagina; the firm, hard cervix and the elastic body of the uterus is felt by the palpating fingers, while between the body and the cervix a soft compressible area, involving the lower segment of the uterus throughout its entire thickness is felt. Hegar's sign is now universally accepted: it has undoubtedly suggested the various other descriptions of the change in consistency subsequently advanced by various investigators.

It was while looking for the Hegar sign for early pregnancy, many years ago, that I succeeded in detecting and developing the sign of early pregnancy which I have taught and employed ever since, and have found to be almost infallible.

I do not know with what constancy and uniformity the changes in the consistency of the body of the uterus, as described by the other observers, can be obtained. I certainly have not detected them to any great extent in the study of my cases while searching for the sign I depend on; I do know, however, that Hegar's sign cannot be obtained in a very large percentage of the cases of early pregnancy (Dickinson claims that it cannot be detected in 40 per cent. of cases), and furthermore that it is present in other conditions, namely, retrodisplacement of the uterus; in the puerperal state; and especially in subinvolution following delivery or abortion.

The change in the consistency in the body of the uterus I desire to call attention to is as follows: Frequently as early as the fifth week, but always in the sixth week, there can be felt in the median line in the anterior wall of the body of the uterus just above the junction of the body and cervix, in other words in the isthmus of the uterus, a circular area the size of the tip of the finger, which presents to the palpating finger the sensation of an elastic fluctuation.

As pregnancy advances this area increases in size in a crescentic manner, until between the third and fourth month, when nearly the entire anterior body, with the exception of the upper crescent of the fundus, partakes of this change, and gives the cystic fluctuating feel to the examining finger. The change appears in the anterior wall of the uterus when the uterus is in the normal position or slightly anteverted, but in extremely retroverted or retroflexed uteri the elastic area appears in the posterior wall, but instead of being perceptible in the fifth or sixth week of pregnancy, is usually felt in the sixth or seventh week.

In incomplete abortion or subinvolution there is a change in the consistency of a similar area of the uterine wall, but while in pregnancy the feel of this area is distinctly elastic or cystic, the sensation obtained in subinvolution and incomplete abortion is very soft and doughy. The two conditions can very readily be differentiated.

It will thus be seen that a familiarity with this sign of pregnancy will also enable one to determine

with a fair degree of certainty whether an abortion is threatened, inevitable, or incomplete. Here again my experience differs from the views generally accepted—that a diagnosis of the death of the ovum in the early months offers considerable difficulty, and can only be made after repeated examination of the uterus proves that it remains stationary in size.

In cases of early pregnancy with symptoms of threatened abortion the area above referred to remains cystic and elastic so long as the ovum is viable, but becomes soft, doughy, and compressible when the ovum dies, and the abortion is inevitable. I have repeatedly advised against a proposed curettage which seemed justified in cases of prolonged bleeding during early pregnancy, when I found the spot in the anterior wall of the uterus to be elastic, and have had the satisfaction of seeing many of the cases I had the opportunity to follow delivered at term. When the area is soft and doughy to the touch, a diagnosis of "blighted ovum" can be made with certainty.

There is another condition which presents a difference in the consistency of the upper and lower portions of the body of the uterus, and that is when a small, symmetrical fibroid is situated in the anterior wall of the uterus, near the fundus. In that case the lower portion is softer than the upper portion of the body of the uterus, but it must be remembered that it is only comparatively so, for while the fundus and body present the hard characteristic feel of a fibroid, the isthmus has the consistency of the normal uterine wall.

However, when a soft myoma, or cystic fibroid, is situated in the anterior wall of the uterus, the cystic or elastic feel elicited in the uterine wall is identical with that of pregnancy, and this is the one condition in which this sign is not of diagnostic value; especially when the soft myoma is associated with amenorrhea, which was present in several cases that came under my observation.

As to the manner of obtaining this sign, it is absolutely essential that bimanual palpation be employed: While the external hand fixes the uterus by counterpressure, and the anterior wall of the uterus from the cervix to the fundus is palpated with the internal finger or fingers, the elastic area in the body of the uterus, immediately above the cervix, will be readily made out; the size of the area will correspond with the duration of pregnancy. I desire to emphasize the fact that the recognition of this elastic area does not require any special skill or dexterity; the ordinary technique and tactile sense requisite for a bimanual examination, combined with a correct interpretation of the change noted in the wall of the uterus, will enable the general practitioner to make a diagnosis with the same ease as the specialist.

Again, the absence of this sign is an absolute indication for the exclusion of uterine pregnancy. In the absence of this change in the uterine wall, pregnancy of more than five or six weeks can be positively eliminated, even in the presence of other presumptive or probable signs.

I will not enter into a full discussion of the differential diagnosis of early pregnancy with regard to the various conditions with which it may be confounded, except that of extrauterine pregnancy, which I propose to consider somewhat in detail.

In every case of suspected ectopic pregnancy the most important aid to a correct diagnosis is the determination of the presence or absence of uterine pregnancy. That becomes apparent when we realize that in all supposed cases of ectopic pregnancy, in addition to the other various signs and symptoms to be taken into consideration, some or all of the presumptive and probable signs and symptoms of pregnancy are invariably present, and the first question to be decided is whether the case is one of uterine pregnancy. With a sign at our disposal which enables us to make a positive diagnosis of the presence or absence of uterine pregnancy, we have eliminated one of the most prolific sources of error in the diagnosis of ectopic pregnancy.

It must be remembered, however, that this sign cannot be depended upon for a differential diagnosis before the fifth and occasionally sixth week of ectopic pregnancy, but fortunately patients requiring attention at so early a stage are comparatively rare.

I have no hesitancy in saying that my ability to exclude uterine pregnancy by this sign has materially assisted me in arriving at a correct diagnosis of ectopic pregnancy in a large number of otherwise doubtful cases, and is largely responsible for my belief that the diagnosis of extrauterine pregnancy can be made with as much certainty as any other pathological condition of the pelvis. In several of my list of cases of extrauterine pregnancy the absence of uterine pregnancy was the only absolute positive indication on which a diagnosis was based and found to be correct.

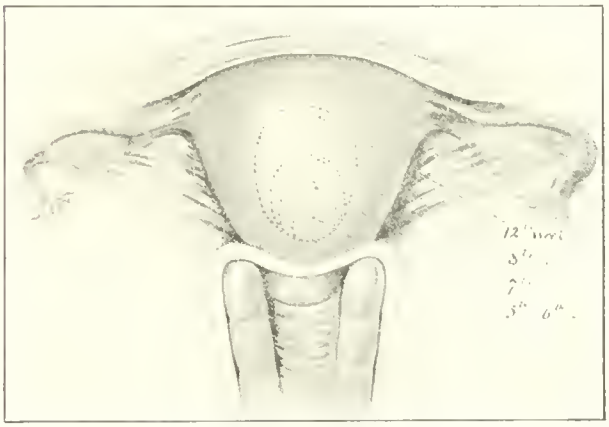

Fig. 3.—Diagramatic representation of the approximate size and shape of the elastic area in the various weeks of pregnancy.

I will take the liberty of citing one case which illustrates this fact most forcibly:

Last summer a lady about 36 years old, who was stopping at a summer hotel in Fleischmanns, Catskill Mountains, and who had previously enjoyed the very best health, after a period of amenorrhea of seven weeks was suddenly seized one morning with severe pain in the left ovarian region, with nausea and vomiting. She had fainting spells, grew extremely pale, her respirations were frequent and shallow, and the pulse became very rapid and feeble; in short, she presented a clear case of internal hemorrhage. Two colleagues, Drs. Ludwig Kohn and I. M. Rottenberg, who were attending her, made a diagnosis of "ruptured tubal pregnancy," and telephoned to me in the city to come up prepared to do a laparotomy.

After heroic hypodermic stimulation and the administration of large quantities of champagne, the patient gradually improved in condition and appearance, so that I found her, late that same afternoon, with an absolutely normal pulse, with good color, and free from pain. The physicians in attendance, both men of large experience and very able diagnosticians, began to doubt the correctness of their diagnosis, and I was asked for a decision.

Examination revealed a slightly distended abdo-

men, but owing to the extreme obesity of the patient, the signs of free fluid in the peritoneal cavity could not be made out with any degree of certainty.

Vaginally, the uterus was found normal in position and slightly enlarged, but with no elastic area in the anterior wall. There was no enlargement of either tube to justify a diagnosis of tubal pregnancy. There was but slight evidence of free fluid in the pelvis. The patient's last child was seven years old, and she had been regular in her menstruation since, except that she had her last period seven weeks previously.

Had this patient been in a hospital, or in her home in the city, I confess I would have been tempted to keep her under observation before deciding to operate; but in view of the fact that she was in a country hotel, and that if her condition became urgent during the night the necessary aid could probably not reach her, an exploratory laparotomy was indicated. To complicate matters, the husband of the patient insisted on a positive diagnosis before he would consent to an operation.

Now here we had a case presenting absolutely no positive signs of tubal pregnancy, and the only symptom to guide us was the amenorrhea. The sudden attack of vomiting and abdominal pain and the shock could also be explained by the fact that after an enema she had had several large evacuations containing mucus and a quantity of undigested material. The fact that I was able positively to exclude uterine pregnancy in this case was the most important factor that led me to confirm and adhere to the diagnosis of ectopic pregnancy.

The operation proved the case to be one of ruptured tubal pregnancy, and the reason for my failure to feel the characteristic distention of the tube, and the marked improvement in her condition subsequent to her collapse, will be found in the specimen, which presents a rupture of a cornual pregnancy of early duration.

As for the cause of this change in the wall of the pregnant uterus, I do not share the opinion of those who claim that it is due to the presence of the ovum and its attachment to the uterine wall. It is generally conceded that the enlargement of the uterus in pregnancy is the result of physiological and not mechanical causes, and that the changes in the organ are reflex in character and begin with impregnation, as evidenced by the enlargement of the uterus in extrauterine pregnancy, and, furthermore, that the hypertrophic process involves not only the muscular fibers and connective tissue, but all the vessels. The branches of the uterine vessels that supply the body of the uterus enter the uterus on a level with the elastic area of pregnancy, and form a loose, dilated, and tortuous plexus, which is probably the first of the important changes that take place in the uterus as the result of pregnancy.

I believe, therefore, that the peculiar elasticity found in early pregnancy is in all probability due to the extreme vascularity of that particular portion of the uterine wall, and to no other cause; but later, however, the fluctuating feel of the body of the uterus is no doubt due also to the presence of the gravid sac.

In emphasizing the fact that the change found by me differs materially from the other signs advanced, and especially from Hegar's, with which it must not be confounded, it is not my intention to detract in the least from the work done in this direction by other observers; that there is a unanimity of opinion that a change in the consistency of the uterus does take place as the result of pregnancy, whatever the interpretation may be, is the best possible proof of its diagnostic value.

The sign I advocate possesses the great advantage that it can be elicited more readily by the general practitioner and the specialist than the other signs, which require especial skill in bimanual palpation for their recognition, and above all because it is uniform and constant in its appearance.

In offering this sign to the general practitioner and specialist, I am doing so, fully convinced that when it is put to a fair test its reliability and value as a means for diagnosis will soon be established.

1289 Madison Avenue.

SYMPTOMLESS MASTOIDITIS, FOLLOWED BY MENINGITIS AND DEATH.*

By A. B. BENNETT, M.D.,
WASHINGTON, D. C.

A very unusual case has recently come under my care, and in view of the very misleading symptoms I beg leave to report its history. Mr. H., male, white, married, age fifty-four, clerk. *Family history* unknown. *Previous history*: He said he had never been ill a day in his life; that he had had one child which had water on its brain, its head was very large, and was tapped and operated upon several times, but it died at an early age. *Present illness*: The last of October he contracted grippe, which was accompanied by severe earache on both sides and almost absolute deafness. He was treated by his family physician until November 10, 1906, when he came under my care. He then complained of severe earache, alternating from side to side, and especially severe at night, causing him much loss of rest. He was also very deaf, not being able to hear the street noises going on about him, and only catching a few words when I fairly shouted into his ear. On examination, his nose, nasopharynx, pharynx, and larynx were very free from inflammation, there being no secretion in the nose, nasopharynx or accessory sinuses. The right membrana tympani was congested in Schrapnel's membrane and along the long process of the malleus. The left membrana tympani was entirely congested and slightly swollen in its superior posterior quadrant. There was no tenderness on severe pressure over either mastoid. With the Eustachian catheter I found the right tube fairly dry, but the left tube contained a great amount of purulent fluid, which was easily aspirated with the catheter, affording the patient immediate though temporary relief and improvement in hearing. At home he douched his ears with hot water every two hours.

This treatment I continued for several days, the pain becoming less; and in my records under date of November 17, one week from my first examination, I have this note, "Much better, no pain, and increased hearing." The congestion of the right membrana tympani soon disappeared, leaving evidence of a chronic catarrhal otitis media of long standing. The congestion of the left membrana tympani also greatly decreased, confining itself almost entirely to Schrapnel's membrane and along the long process of the malleus. From this time on the patient made slow and steady improvement. His general health and appetite improved; he went about on his bicycle and his hearing improved so he could hear distinctly ordinary conversational tones and could hear his clock tick at home. However, he continued to suffer with tinnitus and a "rumbling in his head."

*Reported before the Society of Ophthalmologists and Otologists of Washington, D. C., January 18, 1907.

Repeated examinations of both mastoids failed to reveal any tenderness. During this time he was coming to my office about three times a week for treatment, and his last visit was on Saturday, December 29, 1906.

The following Thursday evening I received a letter from his wife, stating that Mr. H. had been very ill with headache, vertigo, nausea, and vomiting. Suspecting something serious, I wrote her to bring him to the hospital the next day, which she did. There was a marked change in the appearance of the patient; he looked septic and reeled when walking so that he had to be supported. His temperature was 97.4°, pulse 72. There was no change in the appearance of either membrana tympani, and there was no mastoid tenderness on either side. Feeling that there were no indications for operation, I had the patient put to bed on a liquid diet. The next day, Saturday, January 5, 1907, again the local conditions were unchanged. The patient's temperature ranged between 97.4° and 98° and he seemed better, having had no nausea and but little vertigo. Sunday, January 6, 1907, his temperature was between 97.8° and 98.4° and he was very bright and cheerful, laughing and joking with his relatives. About noon on Monday, January 7, he had an attack of nausea, explosive vomiting, vertigo, and a rise in temperature to 101° at 6 P.M. These symptoms continued, the patient tossing about very restlessly, moaning and groaning. At 10 P.M. his temperature had fallen to 98.6°. At 11 o'clock I operated on both mastoids, doing the left side first and finding a tremendous amount of carious bone which was readily curetted from the dura. The dura was incised, evacuating a small amount of serum. The lateral sinus was exposed and found normal. The right mastoid was less diseased than the left, and neither the dura nor the lateral sinus was exposed. The wounds were packed with gauze. The patient's temperature was then 102°, reaching 104° by 8 A.M., 105° by 2 P. M., where it remained until 10 P.M. Shortly thereafter the patient died, never having regained consciousness. Dr. R. S. Lamb performed the autopsy, and the following is his report:

"Post mortem in the case of W. H., male white, age fifty-four. Admitted to hospital January 4. Died January 8, 1907. Height, 5 feet 10; weight, 150 pounds; body well nourished; color, light saffron; eyes, blue. Double mastoidectomy evident. On removing the calvarium the longitudinal sinus was found immensely engorged, as were also the vessels of the dura mater. The removal of the dura exposed a markedly congested pia mater covered with purulent lymph—a diffuse leptomeningitis. The removal of the brain and cutting the spinal cord was attended by the outflow of blood and pus in large quantities, the brain being literally bathed in pus. In the left lateral sinus was found a large, soft, dark clot, in the torcular Herophili a similar clot, and in the right lateral sinus a white disintegrating clot (thrombosis). The base of the skull interiorly was normal, except an absence of the left tegmen tympani. The brain showed a diffuse leptomeningitis over the entire cerebrum and cerebellum with pus in the lateral ventricles. The examination of the other organs of the body showed normal lungs, heart, and kidneys, with congested liver; other organs normal. In conclusion it would appear that the leptomeningitis was of otic origin, via a thrombosed right lateral sinus, as the dura over the absent tegmen tympani showed no pachymeningitis externa." Signed, R. S. Lamb, M.D.

It cannot be possible that this amount of disease came on suddenly, and just when and how the infection took place is surmise. Of the meninges of this brain the parts apparently least affected were those parts just over the ear in the middle fossæ. The engorged vessels of the dura with the lymph deposits on the pia and the presence of pus in the lateral ventricles are similar to the pathology of cerebrospinal meningitis, and many of the symptoms were similar also, but the absence of hyperesthesia, anesthesia, signs of motor irritation, and the cutaneous changes, with the presence of the otitis media and lateral sinus thrombosis certainly warrant the opinion that the cerebral changes were of otic origin. Maybe I have detailed this history somewhat unnecessarily, but it is appalling to me to think that for two months I saw this patient every few days and that the apparently good results from the treatment so completely deceived me as to what was actually going on; and it is my wish to emphasize these few points in closing:

First, that I sincerely regret not making a lumbar puncture before the operation, and that the leucocyte count was not worked up.

Secondly, in regard to the history, to repeat that during the entire attack he never had fever to my knowledge until four hours before the operation; at no time was there any mastoid tenderness; the membrana tympani never perforated or discharged, but the conditions steadily improved, as also did his hearing, and the symptoms of meningitis were the first symptoms that pointed toward operative interference.

The Farragut.

PROLAPSE OF THE RECTUM:

REPORT OF AN OPERATION FOR THE RELIEF OF THE CONDITION IN A DEMENT.

By JAMES K. HALL, M.D.,

MORGANTON, N. C.

ASSISTANT PHYSICIAN NORTH CAROLINA STATE HOSPITAL.

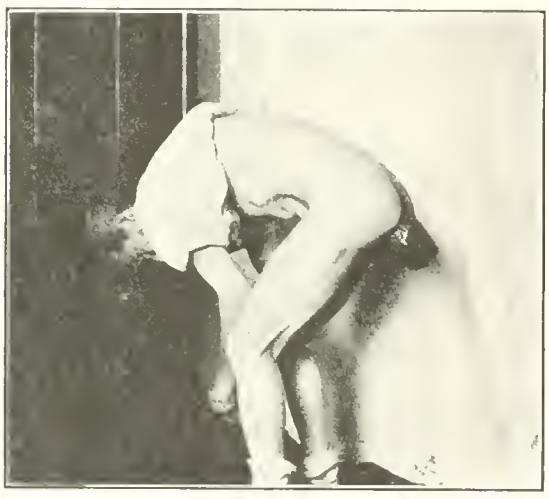
The comparative frequency with which prolapse of the rectum occurs in all classes of society, and the noticeable infrequency in current medical literature of reports of measures successfully adopted for the relief of this distressing and repulsive condition, prompt me to submit the following report of an operation on a young dement who had been suffering for several years from rectal prolapse.

Clinical No. 1753.—G. A., male, white, aged 36, was admitted to the State Hospital at Morganton in 1895. There had been very marked mental disturbance for two years before admission, and his mental development had never been normal. His father, as well as a sister, were epileptics. Before admission the patient had delusions of fear and suspicion, was violent and destructive, and gave his family much concern.

Since admission, mental deterioration has been gradual but progressive. In this article, however, a detailed psychic history of the case, interesting though it might be, would not be in place. Let it suffice to say that for several years after admission the patient enjoyed periods of comparative mental lucidity, during which he was tractable and worked with considerable intelligence. For the past five or six years, however, the periods of depression have been much more frequent and pronounced than formerly, and at such times there has been present always an uncontrollable impulse to take his own life. Five years ago, for instance, the patient ate a quantity of Paris green, but by prompt treatment

was saved from death. Only a short time before this he had attempted to cut his throat with an old piece of steel which he had sharpened by rubbing against a brick wall. Having failed with the poison, he soon made another attempt to cut his throat, but the instrument was too dull. He even tried to throw himself into a rapidly revolving engine wheel, and, at another time, in front of a moving wagon. Less than a month before the operation, which will be described, hemorrhage from a self-inflicted wound on the neck all but had the result he hoped for. Because of this strong suicidal tendency, confinement in the ward and close watching had been necessary for several years. As a result of the confinement, the depression, and the many attempts at self-destruction, his physical health was not robust.

It is impossible to say definitely when the condition began. But it is certain that five years ago a prolapse of such size had taken place that the patient was forced to replace the tumor digitally after each stool. Sphincter power was so strong, however, that recurrence came only with a bowel movement. But as time went by more and more of the rectal tissue descended at each stool, and its reduction became more painful. Finally, the condition became so bad that the patient spent the greater portion of each afternoon in the closet.



The accompanying illustration, made from a kodak taken the day of the operation, will furnish some idea of the size of the mass. It was pear-shaped, quite firm, about eight inches in the long axis, and six transversely. There were on it numerous small abraded and bleeding spots, caused by unskilful methods of reduction. Replacement must have been attended by the most atrocious pain, for the agonized groans of the patient could be heard throughout the ward. And lacking in all the finer feelings though he was, the condition was so repulsive, even to the patient himself, that he sought seclusion in the closet, and refused all aid. Efforts at reduction, although accompanied with difficulty and always attended by great pain, were invariably successful. In the intervals between stools, the sphincters retained the rectum within the pelvis, and there seemed to be no discomfort, even though he spent much of his time on his feet.

About the middle of September the patient made a long gash on the right side of the neck, completely severing the external jugular vein and bringing into view the deeper vessels. Hemorrhage from this wound was severe, and from the time of the accident until the operation the patient was too weak to be up. The heart and lungs seemed to be normal, and nothing was found in the urine to forbid the administration of ether.

Of the many operative measures suggested for the relief of this condition, that one was selected which has for its purpose fixation of the colon, just above the sigmoid, to the anterior abdominal wall. Operation was scheduled for October 16. On the morning of the 15th magnesium sulphate was given in 2 dram doses every hour until the bowels were thoroughly emptied. The abdomen was carefully cleansed in the afternoon, and covered with a weak bichloride dressing. The diet was restricted to milk in small quantities. On the day of operation an ether breakfast was given, *i.e.* a glass of milk and a slice of bread. The bowels were again thoroughly emptied by soapsuds enemata, and the lower bowel was irrigated with liberal quantities of physiological saline solution.

The patient was put on the table at 4:30 P.M. The abdomen was again cleansed with soap and water, ether, alcohol, and a strong solution of mercuric chloride. An incision was made through the abdominal wall on the left side about two inches above Poupart's ligament, parallel with the ligament, and four inches in length. The incision terminated medially at the deep epigastric artery. The rectum was found to be much thickened and indurated, and to the palpating hand it gave the impression of a cone with the apex pointing upward. Other viscera that could be felt seemed to be normal and in their proper positions. The parietal peritoneum for half an inch around the margin of the incision, was separated from the overlying tissue. The colon was then drawn upward and made rather tense. At the upper angle of the incision a strong silk suture was entered just beneath the skin, was passed through the wall to the peritoneum, through the longitudinal band of fibers in the colon, in like manner through the abdominal wall on the opposite side, and firmly tied. This suture, which later became buried, served the double purpose of keeping the rectum and sigmoid on the stretch and the longitudinal bundle of colon fibers in the long axis of the incision. Beginning at the lower angle of the wound, the parietal peritoneum was sutured to the colon. Fine silk was used in a small, curved needle, and the continuous suture was employed. At the lower end of the incision the attachment of the parietal peritoneum to the colon began on the anterior bundle of longitudinal fibers; further up the attachment was about a half inch from the bundle of fibers, and at the upper angle it again approached them. The attachment of the parietal peritoneum to the front and each side of the colon thus formed a kind of diamond-shaped figure, about four inches in the longer axis and an inch and a half at the widest point. The peritoneal cavity was in this way closed. At the lower angle of the incision an interrupted suture was introduced on one side, just beneath the skin, passed downward to the parietal peritoneum, made to catch firmly the anterior longitudinal band of fibers in the colon, and brought through the same constituents of the abdominal wall on the opposite side. Sutures were introduced in like manner about a half inch apart along the entire length of the incision, and were of catgut and silk alternately. They were held by hemostats, and were temporarily left untied. Interrupted sutures of good-sized silkworm gut were now introduced through the abdominal wall, excluding only the peritoneum, and not catching the colon. They were placed half an inch apart. The interrupted sutures of silk and catgut, which had been put through the abdominal wall and also through the band of the colon, were now re-

leased from the hemostats and tied. These became buried sutures, and their purpose was to bring about a third of the circumference of the peritoneal coat of the intestines for a length of four inches into close and firm contact with the raw surface of the abdominal wall—the transversalis fascia—in the hope that strong adhesions might result. The interrupted silkworm gut sutures were now tied, closing the abdominal incision. A dry dressing was applied to the wound, and held in place by adhesive strips and a scultetus. The buttocks were kept in close apposition by adhesive strips applied transversely, thus furnishing some support to the rectum from below. Strychnine, gr. 1-30, was given on the table, and the patient was removed from the operating room at 6:30, in good condition.

It was thought advisable to keep the bowels confined for several days, and to keep the patient absolutely quiet. For this purpose morphine was given frequently. At 9 P.M. on the day of operation gr. 1-6 of morphine was given hypodermically, producing sleep for several hours. At 1 A.M. the next day, to allay restlessness, 1-8 of a grain was again given in the same manner. At this hour the temperature was 101.3°, and the pulse 105. Urine was voided freely, but there was no desire to move the bowels. At noon on the day following operation a teaspoonful of hot water, to be given every hour, was begun, but resulting nausea soon necessitated its discontinuance and the administration of morphine in small doses late in the day. The second night was passed in comfort; urine was voided and flatus expelled. On the second day milk was given every two hours in tablespoonful quantities, but at night there was nausea and vomiting, and morphia was administered. On the third day the temperature did not rise above 101°; the administration of morphine was not resorted to, and liquids—milk, lemonade, and cracked ice in small quantities—were retained. The condition on the fourth day was quite satisfactory. The temperature had fallen to 100°; liquid nourishment was retained, and there was no discomfort. Restlessness and slight nausea were allayed on the next day by morphine, 1-8 of a grain in the forenoon, and a small dose at night. On the sixth day calomel was given hourly in ½ grain doses for six hours in the forenoon. Soon after the last dose there was inclination to bowel movement, and an oil enema was given, resulting in a small stool. Soon afterwards a Seidlitz powder was taken, and within an hour there was a copious stool, unaccompanied by pain or a recurrence of the prolapse. One week after the operation liquids were being taken freely and there was no discomfort whatever. The condition during the three following days, however, was far from satisfactory, and at one time was a source of considerable anxiety. Nausea recurred, there was abdominal discomfort, the pulse became weak, the vitality was lowered, and the patient became restless. Strychnine, gr. 1-30, was ordered given every three hours by hypodermic injection. On the ninth day there was a slight voluntary bowel movement, and vomiting occurred several times. An enema was given on the tenth day, and immediately a very large scybalous mass was expelled, and its removal was attended by great effort and pain.

After this improvement was rapid. Nausea ceased, the appetite improved, and the bowels moved without pain every day. The stitches were removed at the end of two weeks. There were one or two small stitch abscesses, but union was firm. For three weeks after operation the patient was kept under constant watch day and night, and was scarcely allowed to raise his head. During this time the bed pan was used when bowel movements occurred. At the end of three weeks the patient was propped up in bed a few minutes daily. After the fourth week he was allowed to sit up and to walk around a little each day. The bed pan was dispensed with. Several of the buried sutures worked out.

The patient is now, more than four months after the operation, in better physical condition than he has been in for several years. He does not suffer the slightest discomfort at stool, and there has been no sign of a recurrence of the prolapse. Although little improvement was looked for in the mental condition, it is evident that he takes a much more cheerful view of life than formerly. How much the condition had to do in impelling him to self-destruction one cannot say, but one can readily understand how such a condition could make life unendurable, even to an insane man. It is too much to expect the suicidal tendency to disappear, but the pain has been relieved, and its cause removed.

I have no idea of the frequency with which rectal prolapse occurs. An estimate based on the number of cases in this institution would put its occurrence at 1 in every 200 or 300. I have no doubt that the condition exists much more frequently than we think. If every physician were to examine every case of "protruding piles" which he treats without seeing with some kind of ointment, he would doubtless discover many cases of incipient prolapse of the rectum.

My thanks are due the superintendent of the hospital, Dr. P. L. Murphy, for permission to report this case.

ASPIRATION IN OTITIS MEDIA ACUTA.

By PERCY R. WOOD, M.D.,

MARSHALLTOWN, IOWA.

Acute middle-ear suppuration frequently runs a protracted course, convalesces tediously, and leaves in its wake most serious conditions. This arises from failure promptly to control suppuration and limit the zone of infection. While these diseases frequently attack the neurotic and poorly nourished, following exanthematous fevers or influenza, the largest number of cases occur in children suffering from unsuspected adenoids.

Ninety per cent. of middle-ear suppurations arise from pathological conditions in the nasopharynx. The unsatisfactory results so frequently obtained in treatment arise largely through ignorance of these conditions and their relation to this disease. This region should be carefully examined in every instance, not alone with the mirror, but especially with the tip of the index finger, since the eye here does not always furnish complete data. Severe inflammations dependent upon systemic or local irritants might be easily recognized, but the bursa might be filled with hypertrophied lymphoid tissue, or small tufts surround and even encroach upon the Eustachian orifices and the vault still appear healthy, especially to the inexperienced.

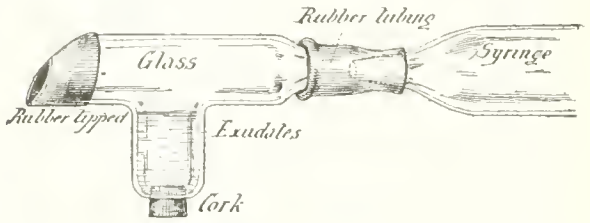
These apparently slight departures from normal play major rôles in the production of middle-ear diseases, favoring inflammatory action and interfering with tympanic drainage and aeration, while their glandular character enables them to retain and transmit pathogenic microorganisms to the middle ear and adjacent structures. The following case is an apt illustration. Johnny B. of Marshalltown, eleven months old, had been suffering six weeks with middle-ear suppuration, none

of the characteristic signs of adenoids being present. Examination disclosed a slight bulging of the bursa and a few tufts of lymphoid tissue overlapping the orifice of the right tube. After their removal and aspiration of the middle ear by means of an original device to be later described, suppuration ceased the third day under appropriate treatment, and complete recovery followed in less than two weeks.

A crisis is established at every onset of an acute otitis media. Infection is invariably a factor, and purulency and chronicity ever-present possibilities. The pathogenic secretions in almost every instance, by traveling paths of least resistance enter the mastoid, and pathological changes here may go on for years without exciting suspicion.

The writer performed an operation this winter entailing entire evisceration of the middle ear and mastoid process with exposure of the brain coverings and venous channels. There was a history of acute suppuration twenty years previously, yet symptoms necessitating active measures appeared but a few weeks before.

In these acute cases, custom prescribes sedatives, anodynes, leeches, counterirritants, and antiseptic medication, coupled with the advice to wait. In the meantime infection is spreading; disintegrating changes taking place in tympanic and mucous membranes, and even if acute symptoms do subside with or without tympanic rupture and resolution does seem to obtain, not infrequently function has been permanently impaired, while the patient, lured to a false sense of security, may be awakened months or years later with chronic middle-ear disease. It is better therefore rather to anticipate and prevent than attempt to cure these conditions. Hence the necessity of some treatment calculated to control inflammation promptly and limit the spread of infection, and so provide against immediate injury and subsequent chronicity.



Middle-ear Aspirator.

An early paracentesis meets these indications by protecting structures from mechanical and pathological action of the secretions, and by relief of tension lessening the chances of mastoid involvement. The wound heals in from three to five days, with no permanent impairment of audition. A solution of equal parts of menthol, cocaine, and carbolic acid applied on an inserted pledget of cotton and retained five minutes renders the operation painless. A large opening is not necessary unless the secretions are exceedingly tenacious, but should be placed right and extend to the floor of the canal.

After drainage is established, removal of the pathogenic exudates is really the paramount issue upon which hinges ultimate success or failure. Merely liberating these does not insure the desired results. They not infrequently have already involved the mastoid, and inspissated particles containing colonies of various cocci invariably cling to the ossicular articulations and the walls and roof of the attics, to the recess of the round window, around the foot of the stapes, and to other sequestered points known to be chosen seats of caries, and there they form pathological foci which develop later. Proof abounds in the chronic cases which are numerous where the tympanic membrane is totally or partially wanting, the ossicles necrosed or absent, and their places occupied by connective tissue bands—all the legitimate fruitage of inadequate treatment.

The writer once enjoyed the privilege of listening to Prof. Politzer on this subject, when he stated that acute middle-ear suppurations usually left traces in the mastoid which remained a constant menace to function, if not to life.

In order to carry out the technique as above suggested an instrument has been specially devised by the writer and called "the middle-ear aspirator." It is manufactured by F. A. Hardy & Co., of Chicago.

It consists of a glass tube three inches long with a reservoir for exudates. The aural extremity tapers and is tipped with rubber, and to the other is attached a syringe with a good sized air chamber. When in place the rubber tipped end seals the opening, the piston is drawn out gently and retained until the reservoir fills, or until no further exudates, blood, or serum escape. By this means these cavities are relieved of vast quantities of pathological secretions which would never entirely drain away or be absorbed, but remain throughout life to threaten the integrity of the parts. While this procedure does not exactly sterilize these parts, by the removal of vast quantities of microorganisms their preponderance over the living tissues is destroyed. Another feature not to be ignored is the favorable influence exerted by the blood-letting principle applied by the instrument. It relieves congestion, soothes pain, and hastens convalescence.

When the inaccessibleness of these regions and their vulnerability to necrotic action is considered, as well as the large percentage of cases which for these reasons become chronic, the practicability of this procedure is beyond question.

When through aspirating the auditory canal is sterilized, a current of warm camphorated vapor is sent through from the Eustachian side, the parts are dusted with boracic acid powder and packed loosely with iodoform gauze, and the pharynx is swabbed with a 2 per cent. solution of silver nitrate. This dressing and treatment should be renewed daily at first. Permanent recovery with reestablished normal function usually ensues within ten days.

ARRESTED MENTAL DEVELOPMENT.

By HUBERT RICHARDSON, M.D.,

BALTIMORE, MD.

LATE PATHOLOGIST TO MOUNT HOPE RETREAT, LECTURER ON NEUROLOGY AND PSYCHOLOGY AND ON PHYSIOLOGICAL CHEMISTRY, UNIVERSITY OF MARYLAND; PATHOLOGIST TO THE MARYLAND ASYLUM AND TRAINING SCHOOL FOR FEEBLE-MINDED CHILDREN.

Arrested mental development is a misfortune to both parent and child, calling for the physician to put forth all his efforts to discover the cause and if possible remedy the condition. It is probable that, notwithstanding the statistics, a very large proportion of our feeble-minded children are not heirs to the sins of omission and commission of their parents, but that the etiological factor of their defective mentality is of postnatal origin. Acute diseases in the first three years of life

are often the cause of lesions which permanently affect both the mental and the physical development of the child. It has been a matter of common observation that after a severe attack of the acute diseases of childhood, such as measles, scarlet fever, whooping cough, etc., there has occurred a gradual decrease in mental growth; the child may not be stupid or apathetic, but his mentality remains behind for his years, described as weakness of character or childishness, he having the normal mentality of a child much younger in years; puberty is delayed, and as he grows older it is true his mind also grows, but he never arrives at true mental maturity. In other cases the child deteriorates, becoming imbecile or even idiotic; in which case it is more than probable that during the acute disease from which he has suffered his thyroid has become infected, resulting in a cirrhotic condition of the gland, and consequent insufficiency; at puberty, when extra demands are thrown upon the thyroid, the symptoms become accentuated, a myxedematous condition commencing which, unless treated, will proceed to a cretinic condition from which there is little or no hope of recovery.

Another cause of arrested mentality is found in defects of assimilation and metabolism. Cases occur in which, from some acute disease, the gastric juice fails to contain either hydrochloric acid or the ferments; the exciting factor to the intestinal secretions not being present, the digestive process is deranged, and both physical and mental development are arrested for lack of nutrition. These patients usually have an uncontrollable diarrhea, with poor assimilation of fat.

Still another cause is to be found in circulatory defects. The cardiac energy may have been affected, and on taking the erect position there is not sufficient force to drive the blood to the brain. These children are usually well developed in the lower trunk and limbs, but the head and expression give the observer the impression of feeble development. The quantity of blood required by every organ can be divided into three portions, the first required for food, the second for functioning, and the third for growth. While the child remains recumbent the circulation is about equal all over the body, but on his taking the erect position the heart is unable to force the blood to the vertex, and though it may send enough for nutrition, yet not enough for perfect functioning and growth; in cases of angioplasia when the arteries are reduced in caliber this condition exists.

Acute disease may have affected the special senses, the child does not commence to walk or talk till long after the usual age, his limbs may be well nourished, but he lacks the nervous force from the cerebral centers; when he does commence to talk there are defects of speech which may be due to structural irregularities in the peripheral organs of speech, the tongue, palate, lips, teeth, nostrils, or pharynx, or in their nerve supply. The intellectual centers of the brain are in close connection with the central or cerebral speech mechanism, language and thought are inseparable; to think is to speak low, to speak is to think aloud. It is impossible to learn to speak without calling into requisition the sense of hearing, and the child cannot talk or think if its hearing is defective, which is often due to infection of the auditory apparatus. Those children whose hearing is defective may appear bright in certain lines, they may be able to make their every want understood by pantomime, but their mental development is permanently retarded unless the auditory defects can be remedied. Many children can be found in every asylum whose enfeebled mentality is due to ear disease, the result of postnatal infection. Defective sight, owing to the strain upon the eyes, often arrests the mental development of the child, and in a few cases produces epilepsy which in its turn increases the mental hebetude. There is every probability that insufficiency of the suprarenal glands is also a cause of arrested development, and absence of the testicular secretion has also a pathological effect upon both body and mind.

Intestinal parasites are often a cause of stunted growth, owing probably to the fact that they produce an antibody which destroys enterokinase, the ferment whose function it is to convert the inactive trypsinogen of the pancreatic secretion into active trypsin, thus striking at the very foundation of intestinal protein digestion.

Much can be done for those whose development has been retarded by antenatal conditions produced by disease of the mother during pregnancy. As the fetal liver is the organ which receives the maternal toxins, it is the organ requiring the postnatal attention of the physician. The right side of the heart during fetal life is the principal factor in the circulation, and antenatal valvular lesions are almost invariably in the tricuspid valve. In every case attention to the digestive tract is of the first importance, as without nutrition, no matter what other lesions may exist, development, either mental or physical, is impossible.

819 Park Avenue.

Operations During Typhoid Fever.—At a recent meeting of the Liverpool Medical Institution (*Lancet*, January 12, 1907), Dr. W. T. Thomas reported two cases of operations during typhoid fever, one for perforation, the other for appendicitis, in both of which recovery took place. He called attention to the fatal character of perforation unless surgically treated, when the recovery rate was 30 per cent. or more. Although in many cases the diagnosis was uncertain, it would be wiser to explore (under local anesthesia) than to wait until general septic peritonitis had set in. The treatment of the perforation by quick suture or the formation of a fecal fistula appeared to be the two alternatives—fancy work such as enterectomy with end-to-end anastomosis was not to be recommended; enterostomy had the further advantage of draining the typhoid intestine and keeping it at rest. Dr. F. T. Paul referred to a case in which a perforation twelve inches from the cecum occurred three months after the onset of typhoid fever. In this case the ulceration was so extensive that the perforation could be closed only by excising it and the patient died nine days after the operation. Dr. T. C. Jones mentioned a case in which he had operated successfully last July. A Lascar boy was taken to the Liverpool Infirmary at the end of the second day after perforation of a typhoid ulcer. Simple suture of the ulcer was performed and the abdomen was cleaned of intestinal contents. The boy was transferred to his ship three weeks afterwards. Perforation was rare in Hindus and the infection was comparatively slight. Dr. R. W. Murray said that better results from operative interference would probably be obtained if, as a general rule, the bowel at the point of perforation was brought to the surface and a fecal fistula temporarily established. Such an operation could be quickly performed and would have the great advantage of permitting the inflamed bowel to rest.

New York, April 13, 1907.

THE EFFECTS OF MATERNAL GONORRHEA ON THE OFFSPRING.

It is a matter of quite widespread popular belief that gonorrhea in the mother has no deleterious effect on the offspring beyond a possible ophthalmia. This, of course, is serious enough, although it may ordinarily be avoided by prophylactic means, but a recent investigation by Lobenstine and Harrar, reported in the *Bulletin of the Lying-in Hospital*, December, 1906, shows that in addition to the production of an ophthalmia, the general nutrition of the infant is likely to fail when the pregnant woman is suffering from gonorrhea. The investigation in question was conducted at one of the large maternity hospitals, where an extensive material was available for the purpose. The work is based upon comparisons made between fifty babies of gonorrheal mothers, one hundred and fifty babies of normal mothers, and fifty babies of non-gonorrheal mothers who presented more or less marked elevations of temperature. The babies in this series of cases were all breast-fed and the period of observation extended over the first ten days of infant life. The gonococcus was demonstrated in the genital tract of each of the mothers alleged to be suffering from gonorrhea.

A detailed study of the results presented by the authors of the paper shows conclusively that the disease process referred to exerts a well marked deleterious influence on the nutrition of the fetus. The average birth weight of the babies of gonorrheal mothers was found to be 297 grams less than those of normal mothers and the average initial loss in weight was also more pronounced in the former than in the latter. Another important fact was that the amount of the loss which was regained by the tenth day was much less in the gonorrheal than in the normal babies. The former also suffered more from fever and intestinal disturbances than the latter. Gonorrhea in the mother is evidently also a frequent cause of premature births, for in this series of cases it amounted to about twenty-two per cent., whereas under normal conditions it occurs only in somewhat over two per cent. Fever in the mother, no matter what its cause, always exerts an unfortunate effect on the child, and we find that the loss in weight which the latter experiences is always very slowly regained.

The writers do not think, however, that the interference with the infant's nutrition is due to any specific toxins excreted by the milk of the gonorrheal mother, but rather that it is due to local effects of the disease, which vitiates the normal nutrition of the fetus, and also to the presence of elevated temperature during the puerperium of the mother. These results are of considerable practical interest as demonstrating the extreme care which should be exercised in treating any gonorrheal inflammation which may be present in the mother during her pregnancy, for the effects of this disease have been shown to exert a general as well as a local effect on the offspring. A knowledge of these facts needs general diffusion, and the deleterious effects of the venereal diseases not only upon those immediately afflicted, but on their offspring, is a subject which demands increased attention from the laity as well as from the medical profession.

THE DERMATITIS CAUSED BY THE BROWN-TAIL MOTH.

DERMATOLOGISTS, and more especially entomologists, have long recognized that contact with the larvæ of certain of the lepidopterous insects is capable of inducing a more or less annoying form of dermatitis, but, in this country at least, the species that possess this property are not very well represented, and until recently the subject has not attracted a great deal of attention. Of late years, however, one of the worst offenders in this respect, the so-called brown-tail moth, *Porthesia* or *Euproctis* or *Liparis chrysorrhœa*, has become so common in certain parts of New England, and appears to evince so decided a propensity to enlarge its habitat that the subject seems well worthy of consideration.

Among the first to point out the part played by the caterpillar of this moth in the production of a peculiar urticarial type of dermatitis frequently seen in the districts infected, were Drs. J. C. White and E. R. Meek, who presented communications to this effect in the *Boston Medical and Surgical Journal* in 1901. It was suggested that it was the hairs of the caterpillar, which are very brittle and easily detached, that were the source of the irritation, and the question arose as to whether the dermatitis was simply the result of the mechanical action of the hairs or was due to a poisonous substance conveyed by them into the skin. Fernald and Kirkland, the authors of the Massachusetts State Board of Agriculture bulletin on the brown-tail moth, as the result of an examination of the hairs, cocoons, and molted skins of the insects made by Mr. F. J. Smith, chemist of the Gipsy Moth Committee, inclined to the view that the effect was purely a mechanical one. As the result of a very thorough investigation of the subject by E. E. Tyzzer (*Journal of Medical Research*, March, 1907), this belief appears untenable, however. He agrees with the preceding observers that the dermatitis is produced by a specialized form of short, barbed spines termed "nettling hairs," but demonstrates that the actual morbific agent is a toxic substance which greatly aggravates the irritation produced by the penetration of the hairs. The nettling hairs are straight, tapering, needle-pointed shafts, provided with numerous recurrent barbs and measuring on the average 0.1 millimeter in length and 0.005 millimeter in thickness at the larger extremity. No pore is visible in the hairs, but their behavior in regard to staining

fluids, and other considerations, make it seem likely that the poisonous substance is contained in a cavity in their interior. They develop in the caterpillar, and are present even in very young specimens. In the process of manufacturing the cocoon the hairs are rubbed off the caterpillar and enter into the structure of the cocoon, and are also found mingled with the long hairs of the brown tuft on the tail of the moth, though it is probable that they simply become entangled in the scales of the moth as it works its way out through the cocoon, and are thus all primarily derived from the caterpillar. They also occur in the egg masses and in the winter webs, and are blown about in the air.

By control experiments with finely comminuted glass wool and the barbed hairs of the harmless tussock moth caterpillar, Tyzzer was able to show that the mechanical irritation alone of the hairs was not sufficient to give rise to the clinical picture of the dermatitis, and the discovery of a peculiar reaction caused when they were added to blood indicated that a soluble chemical substance must be present in them. It was found that if a number of nettling hairs were placed in a drop of blood between a slide and cover-glass, an immediate change took place in the red blood corpuscles. They at once became coarsely crenated, and the rouleaux were broken up in the vicinity of the hair. The corpuscles decreased in size and the coarse crenations were transformed into slender spines which rapidly disappeared, leaving the corpuscles in the form of spheres, the light refraction of which contrasted them sharply from the normal corpuscles. The change of form, in addition to a slight shrinkage, caused the red blood corpuscles to appear much smaller than normal. This reaction takes place so rapidly when the fresh, active, nettling hairs are used that the eye cannot follow its various stages, but by treating these hairs in various ways, the time of this reaction may be slowed so that all stages of transformation may be seen. Control tests with similar minute foreign bodies of different origin were negative.

The next step lay in the demonstration of the fact that the hairs could be deprived of their specific irritating properties by heating them to 115° C. for one hour, though their structural integrity was not impaired by baking at a much higher temperature than this. It was further found that although this active substance was refractory to a large number of solvents tested, it could be extracted with distilled water at 60° C. and by dilute alkaline solutions at room temperature, the hairs so treated becoming inactive. The stabile nature of the substance contained in the hairs afforded an explanation of the fact that the hairs adhering to empty cocoons retain their irritating properties indefinitely, and that underclothing hung to dry in the neighborhood of infested trees and then packed away for a year has been known to produce dermatitis when worn again.

The reaction of the human skin to the nettling hairs of the brown-tail moth varies greatly with different individuals. When these hairs are rubbed upon the skin there is immediately, with most persons, considerable itching, and the inoculated area rises up in the course of fifteen or twenty minutes in the form of a wheal about which there is considerable reddening that changes to white when the skin is stretched. The reaction, however, is not always so prompt to appear, and the severest process observed by the author showed nothing for a period of eight hours after the inoculation. The nettling hairs, even when rubbed into the skin of other individuals, produce only slight reddening, or perhaps very slight elevation, and practically no discomfort. Whether or not decreased alkalinity of the blood forms a factor in the insusceptibility of these persons, is only a matter of conjecture. The dermatitis, as it occurs naturally, is of two types, according to the manner of acquisition. If, for instance, a caterpillar is felt crawling over one's neck, and is thereupon slapped or crushed, and the part afterward thoroughly rubbed and scratched, a marked local dermatitis develops in which the lesions are confluent. There is local reddening and thickening of the skin with the formation of papules or vesicles, as the case may be. A patient in this condition is liable to seek the advice of a physician. On the other hand, if the nettling hairs are distributed by a breeze to underclothes as they hang drying, the dermatitis which results from wearing these clothes is of the nature of a scattered urticarial rash. The lesions in such a case are in the form of small discrete papules which, if not scratched, often show at their summit a tiny vesicle filled with clear fluid. They are generally more numerous on parts of the body where the skin is soft. Many persons having such rashes never consult the physician. Warm, muggy weather aggravates the condition; the reason is that the epidermis is then kept moist by perspiration, and becoming softer favors the penetration of the nettling hairs. The duration of the dermatitis is variable, but the individual lesions usually heal in from seven to ten days. The severest forms are seen during May and June, as it is at this time that the caterpillars reach their maturity.

By microscopical examination of sections of infected tissue from his own person and from experiment animals Tyzzer was able to show that the pathological process in the skin consists of necrosis of the epidermal cells around the nettling hairs, the formation of spaces or microscopic vesicles in the epidermis at the site of injury, and inflammatory changes about the vessels of the corium. Mice inoculated with active nettling hairs presented lesions characterized by a large amount of fluid exudate, while those inoculated with inactivated nettling hairs showed merely inflammation of the nature of a reaction due to the mechanical injury brought about by these elements.

These ingenious investigations of Tyzzer's throw light on the nature and pathology of a condition which, while not very serious, is yet most annoying, and which is likely to become of interest to more practitioners from year to year, as the insect extends its area of activity. They also show that there are more than merely economic reasons making it desirable to spare no efforts to exterminate the pest.

Uniformity in Pharmacopœias.—The Belgian Academy of Medicine at a session devoted to a discussion of the discrepancies in the official pharmacopœias in use in the different countries adopted a resolution recommending the government to take steps toward the formation of an international commission having for its object the establishment of a permanent bureau to work for greater consistency in this respect.

STRONTIUM BROMIDE IN THE TREATMENT OF EPILEPSY.

It will not be gainsaid that a careful regulation of the entire mode of life has a most beneficent influence upon the course of epilepsy, but, despite the well-known objections to the use, and especially the continued use, of the bromides in the treatment of that disease, such a therapeutic course is often rendered necessary for the purpose of diminishing the frequency and lessening the severity of the attacks.

The bromides, like other agencies potent for good, are also capable of doing much harm, and it is the part of the intelligent therapeutist to avail himself of the one influence and to avoid the other. The bromides are serviceable, especially in the treatment of major epilepsy, and they exert little or no good effect on the course of minor epilepsy. Even in cases in which they do good, the bromides sometimes lose their effect, after a time, and it has been found that a combination of two or more bromides is at times more useful than one alone. Moreover, a change in the drug employed is often sufficient to continue a good effect once begun. It is, therefore, advantageous to have at command as large a variety of efficacious agents as possible. Distinct advantages are claimed for the several bromides with respect to solubility, tolerance on the part of the stomach, amount of combined bromine, hypnotic effect, and influence on reflex activity. The potassium-salt is, perhaps, the one most commonly employed, but the sodium salt is more soluble, less irritating, and less depressing to the heart. These advantages of the sodium salt are shared also by the strontium salt, which has at times proved more successful therapeutically than the former.

For the purpose of testing the comparative usefulness of strontium bromide, Dr. J. M. Bennion (*Lancet*, January 5, 1907, p. 10) administered this drug in doses of thirty grains in an ounce of water thrice daily to twelve male and ten female insane patients suffering from epileptic seizures, all other conditions remaining as they had been previously. It was found that strontium bromide acted better in controlling the number and the severity of the attacks than the mixed bromides of potassium and sodium. It rarely caused depression, and in no instance was its use attended with a cutaneous exanthem. The good effects appeared to be more marked in females than in males. It is reasoned that if such good results could be obtained under the conditions of the test, certainly not less good ones are possible in cases of less aggravated character.

The Economic Aspects of Bovine Tuberculosis.

Farmers as a class are certainly far from unintelligent, and there is no doubt that when they shall have been brought to realize the menace, not only to public health but also to agricultural prosperity, involved in a hostile, or even only an indifferent, attitude toward the effort to exterminate tuberculosis in cattle, they will be only too willing to aid those who are trying so hard to convince them of this necessity. We trust the time will soon come when so misguided an exhibition of feeling as that shown by the meeting of Massachusetts farmers who recently assembled in Swansea to protest in no measured terms against the local Health Board's recommendation that the dairy herds of the vicinity be examined for the presence of tuberculous animals, will be an impossibility. Self interest alone should point out the wisdom of accepting, if necessary, some immediate sacrifice in order to avoid the infinitely greater future loss. While it is difficult to estimate with any approach to accuracy the losses to the farmers as a whole from a disease like tuberculosis, concerning which the statistics are still so incomplete, the figures supplied by the Committee on the Prevention of Tuberculosis of the Charity Organization Society of the city of New York are very suggestive. It is stated that there are now approximately 11,000 carcasses of beef and 65,000 carcasses of hogs condemned each year by the Federal meat inspectors on account of tuberculosis. One should not be far wrong in estimating the loss on these carcasses at present prices as $40 each on the beef and $12 each on the pork, according to the United States Department of Agriculture. We should therefore have as the net annual loss from the condemnation of carcasses $440,000 for beef and $780,000 for pork, or a total of $1,220,000. This statement, however, does not include the 647 parts of beef carcasses and the 142,105 parts of hog carcasses which it was necessary last year to condemn for the same cause, and the approximate value of which cannot be ascertained. In addition to the carcasses condemned by Federal inspectors, there are a considerable number condemned by State and municipal inspectors. These are mostly carcasses of dairy cattle killed in the work of suppressing tuberculosis, or of cows no longer profitable in the dairy which are sent for slaughter to the smaller abattoirs. The aggregate number of these has not been ascertained, but in some years it has amounted to several thousand carcasses. The losses to the dairy industry from tuberculosis have been enormous from decrease in milk and depreciation and death of animals. The dairy herds have been affected to a greater extent than any others, and the infection as a rule spread through the cows of a herd until 50 per cent. to 80 per cent. of the animals were affected. In the early stages of the disease the product of the cows is not visibly lessened, but as the tuberculous process develops the animals often become feverish, their milk is diminished in quantity, and they lose flesh and are no longer profitable. The losses from shrinkage of the milk and from the destruction of so many cows must be tremendous, but they have never been definitely determined.

The After-Treatment of Cases of Excision of the Rectum.

In a recent paper by Professor Hochenegg (*Deutsche Zeitschrift für Chirurgie*, vol. 85, 1906) there are noted some particularly valuable suggestions for overcoming the objections attendant upon the operation of excision of the rectum by the sacral route. He thinks that the successful outcome is more especially dependent upon the after-treatment in this than in any other operative procedure. His own experience with this operation extends over a large number of cases, so that his advice may be taken without hesitation. Among the first precautions to be taken with these patients is to keep them on the side rather than on the back, and to have the pelvis at a lower level than the trunk. This prevents the intestinal contents or those of an abcess from getting into the general peritoneal cavity in case rupture takes place. Urinary retention after

rectal operations is frequent, and in cases where the rectum has been excised there is plenty of room for the bladder to be distended backwards, so that the condition may escape attention for a longer period. The patients, of course, do not notice the distention on account of the pain from the wound, or because they are still under the influence of the anesthetic. Even after the catheter has been introduced the bladder will be found to contract with difficulty, so that cystitis is frequent. The latter is favored, moreover, by the close proximity of the posterior surface of the bladder to the operative wound. Systematic bacteriological examination of the urine in these cases has shown that the wall of the bladder may readily be penetrated by infectious material, so that vesical sepsis is often found to be the cause of death in these patients. Careful catheterization should therefore constitute one of the leading features of the after-treatment. Great care must also be exercised in moving the bowels for the first few times, but later on thorough evacuations must be secured so that the general nutrition of the patients may be improved. The results from this operation are at best none too good, so that any suggestions of this kind from so eminent an authority deserve careful consideration.

Typhoid Inoculation in the English Army.

A report on the progress of typhoid inoculation in the English army was recently made by Lieut. Col. W. B. Leishman before the London Pathological Society, as reported in the British Medical Journal of March 23. The author stated that numerous vaccines had been prepared from typhoid bacteria killed at different temperatures, by various chemical agents, by desiccation, etc., and their effects tested by measurement of the various protective substances which developed in the blood of inoculated animals. In several instances, where the results appeared promising, similar tests were carried out on man. The vaccine at present in use was described, and an account given of the mode of preparation and standardization, which had been somewhat modified from Sir A. E. Wright's methods in the light of the experimental work referred to. The bacteria were still killed by heat, but the temperature had been reduced to the minimum degree which would insure death in one hour—53° C. The deleterious effects of higher temperatures had been clearly brought out by some of the experimental work, and it was suggested that the comparatively poor results obtained in some instances in the past may have been due to overheating of the vaccine. The system adopted for ascertaining the protective value of the inoculations was then described, and the result of the inoculation of one regiment was given. This regiment, the only one which had been exposed to a severe epidemic of typhoid fever since the modified vaccine had been in use, had 147 officers and men inoculated out of a strength of 509. They had 62 cases of typhoid infection, with 11 deaths. All of these occurred among the uninoculated with the exception of 2, both being men who had refused the second inoculation; both of these men recovered.

Indications for Operation in the Presence of Diabetic Gangrene.

From a study of the most recent literature, Klemperer (*Therapie der Gegenwart*, January, 1907) concludes that the presence or absence of acidosis constitutes the most valuable differential sign. Diabetic patients without acidosis are not subjects for surgical interference if gangrene supervenes. An expectant treatment is indicated, carefully restricted diet, and patient waiting for the line of demarcation to form. The latter process may perhaps be hastened by the application of proper dressings and by Bier's procedure. In diabetic subjects who present no acidosis, but have a marked albuminuria or signs of granular atrophy, a high amputation should be undertaken as soon as possible after evidences of gangrene appear. Where acidosis is present the patients are likewise to be immediately operated on, as they are otherwise sure to succumb. It is immaterial whether the acidosis was already present or did not appear until after the introduction of a diet free from carbohydrates and a high amputation must be done, even when the original focus is very small.

The Dangers of Elixirs.

Simple elixir, so called, has been adopted as a common vehicle in prescriptions intended for children, yet it is probable that but few physicians realize that this elixir contains a considerable proportion of alcohol which under other circumstances they would hesitate to administer. It remains for a pharmacist to call attention to this fact, and to show that the ordinary doses of the preparation may be productive of considerable harm in those of tender years. Mr. E. F. Heffner, in a paper read at the twenty-ninth annual meeting of the Pennsylvania Pharmaceutical Association, cited a number of common prescriptions in which this might occur. Thus sodium bromide is very often administered in the proportion of one grain to the teaspoonful of simple elixir, every hour or half hour, which means that the child, often less than a year old, is getting about a quarter of a teaspoonful of alcohol at every dose, or the equivalent of two teaspoonfuls of wine or over half a teaspoonful of whisky or brandy. In older children correspondingly larger doses are given, which are not only harmful in themselves, but also counteract the sedative effects of the bromide. Another common prescription contains chloral and bromides in simple elixir, which makes a bright, clear, and palatable solution. But the fact is overlooked that there is a chemical incompatability of chloral and alkaline bromides in alcoholic solution, for on standing the chloral alcoholate will come to the top in a clear layer of about the same color as the rest of the mixture. Unless shaken, the patient is likely to get all the chloral in one dose. These examples need no comment, for the dangerous effect of alcohol in children is of common knowledge, but as Heffner truly states, it is well that the prescribing mind be occasionally refreshed in cases of this kind. In order to avoid any possible danger he advises the use of an aromatic water and simple syrup as a vehicle in prescriptions of this nature.

News of the Week.

The United States Civil Service Commission announces an examination on June 13-14, 1907, to secure eligibles from which to make certification to fill at least five vacancies in the position of medical interne (male), at $600 per annum each, with maintenance, in the Government Hospital for the Insane, Washington, D. C., and vacancies as they may occur in any branch of the service requiring similar qualifications. The department states that it reserves the right to continue or terminate appointment at the end of one

year, or to promote the appointee at the expiration of that length of service. The examination will consist of the following subjects, weighted as indicated: Letter-writing, 5; anatomy and physiology, 15; chemistry, materia medica, and therapeutics, 10; surgery and surgical pathology, 20; general pathology and practice, 25; bacteriology and hygiene, 10; obstetrics and gynecology, 15. Two days will be required for this examination. Men only will be admitted. Age limit, 20 years or over on the date of the examination; candidates must be graduates of reputable medical colleges. This examination is open to all citizens of the United States who comply with the requirements. Intending candidates should at once apply to the United States Civil Service Commission, Washington, D. C., for application form 1312.

Conference of the Illinois State Board of Health with the Officers of Medical Societies of the State of Illinois.—This conference was held in Chicago, April 5. Methods looking toward improvement of the public health, the advancement of medical education, the advancement of the interests of legally qualified physicians in the State, were considered. Committees on the following subjects were appointed: Reciprocity, Medical Education in Illinois, Relation of the State Board of Health to Local Health Boards; Examination of Candidates and the Method Pursued in Connection with the Administration of the Medical Practice Act in the Case of Unlicensed Practitioners; To Promote Cooperation Between State Medical Societies and the State Board of Health; Cooperation Between the Four Schools of Medicine. The conference adjourned to meet again April 24, at which time the chairmen of these committees will submit their reports for discussion and ratification or rejection.

Pennsylvania State Hospital for the Criminal Insane.—Plans are under consideration for a new State Hospital for the Insane in Pennsylvania, and options have been obtained upon several hundred acres of land adjoining the site of 600 acres presented to the State by the Delaware and Hudson Railroad. The sum of $150,000 is to be appropriated by the Legislature for the erection of an administration building, which will contain the offices and quarters for the executive officers and accommodations for probably 100 patients. It is the intention of the commission having the matter in charge to build an institution capable of accommodating 1,000 patients at a cost likely to be more than $1,000,000. The New York State Hospital for the Criminal Insane at Matteawan is to be taken as a model, and such improvements will be made as have been found desirable since the building for that institution was constructed.

A New Milk Commission.—A commission consisting of five members has been appointed by Mayor McClellan to consider the advisability of rendering pasteurization of all or a part of the city's milk supply compulsory. The commission is to investigate the entire subject of the milk supply and make recommendations in regard to whatever measures seem necessary to insure its purity. The commission has the following members: Dr. Joseph D. Bryant, Dr. T. Mitchell Prudden, Dr. Rowland G. Freeman, Dr. L. Emmett Holt, Dr. Abraham Jacobi.

The XVIth International Medical Congress.—At the last International Medical Congress held in Lisbon, Budapest was selected as the next place of assembly, and the preliminaries are already in progress. His Majesty the King has assumed the patronage of the congress, and the State and the municipality have each contributed the sum of 100,000 crowns to defray the expenses. Numerous committees and subcommittees have already been appointed, and it has been decided to have twenty-one sections to the congress. The date of opening has been fixed for August 29, 1909, and the sessions will be continued until September 4. The first circular, which will contain much information in regard to details, as well as the statutes, will be ready for distribution in the course of this year. The President of the Congress is Professor Calman Müller, and the General Secretary, Professor Emil Grósz, announces his readiness to give information to inquirers. His address is Budapest, Hungary, VIII. Esterházy-utcza 7.

Mexican Medical Congress.—The Medical Society Pedro Escobedo of Mexico is organizing its second biennial congress to be held in Mexico City, May 28, 29, 30, and 31. President Diaz is honorary president and will open the congress. The president of the society is Dr. Lopez Hermosa, and the secretary is Dr. Enrique Aragon. There will be eleven sections, each comprising two special subjects.

The XLVth International Congress of Hygiene and Demography.—Those in charge of this congress, which is to be held in Berlin, September 23 to 29, have decided to make a special effort to render it possible for those who take part in the congress to see as much as possible of the various public institutions of Berlin and its suburbs. Accordingly, the scientific sessions will always be over by two o'clock, in order to leave the afternoons free for sightseeing. A list of one hundred institutions has been prepared, which may be visited either informally or in groups under the guidance of a qualified authority. A guide book in three languages has also been composed which contains short descriptions of all these institutions.

The XIIth Congress of the German Gynecological Society.—At the congress of this Society to be held in Dresden, May 21 to 25, the following have been selected as topics for general discussion: 1. "The Indications, Technique, and Results of Operations Increasing the Size of the Pelvic Outlet;" 2. "Asepsis in Gynecological Operations;" 3. "The Midwife Question."

The Second International Congress of Physiotherapy will be held in Rome, Italy, on October 13, 14, 15, and 16, 1907, under the presidency of Prof. Guido Baccelli. The general secretary is Prof. Carlo Colombo, Via Plinio, 1, Rome. The officers of the American Committee have been appointed as follows: *President*, Dr. Francis B. Bishop of Washington, D. C.; *Secretary*, Dr. Wm. Benham Snow of this city; *Treasurer*, Dr. Albert C. Geyser of this city. A special committee has also been appointed as follows: Dr. Fred H. Morse, mechanotherapy; Dr. Margaret A. Cleaves, phototherapy; Dr. Geo. C. Johnston, radiography; Dr. Wm. James Morton, radiumtherapy; Dr. Morris W. Brinkman, rhythmotherapy; Dr. Chas. Denison, climatology; Dr. G. Betton Massey, massive cataphoresis; Dr. David E. Hogg, thermotherapy; Dr. Edward C. Titus, electrotherapy.

Mortality in Chicago.—According to the weekly bulletin of the Chicago Health Department, during the week ended March 30, 744 deaths were reported, equivalent to an annual

death-rate per 1,000 of 18.40. The death-rate for the corresponding week of 1906 was 14.80 per 1,000. Pneumonia caused 172 deaths; consumption, 85; heart disease, 55; nephritis, 45; violence, including suicide, 40; cancer, 34, and acute intestinal diseases, 30.

Mount Sinai Hospital.—A considerable number of adjunct physicians and surgeons will soon be added to the visiting staff of Mount Sinai Hospital. The new appointees will rank as assistants to the present adjunct attending staff. The appointments to be made will increase the visiting staff of the hospital by seventeen men, and will affect the following departments: general medicine, general surgery, gynecology, genitourinary surgery, otology and ophthalmology, pediatrics, neurology, and dermatology.

Osteopathy Bill.—An amendment to the osteopathy bill has been adopted by the Assembly at Albany, providing that osteopaths otherwise eligible under the Whitney bill shall pass an examination in surgery before being allowed to practice surgery.

The City of Montreal, owing, it is alleged, to the expense, has decided to discontinue its medical inspection of the pupils in the public schools.

A New System of Identification.—Dr. Prager, an Austrian army surgeon, who has made a special study of the physical characteristics that may be used as means of identification, suggests a system based on variations in the conformation of the palate. He maintains that this method can be used more effectively than that founded on the finger-print principle.

Fire at McGill University.—The MacDonald engineering building of McGill University, Montreal, which was erected about fifteen years ago at a cost of $500,000, was completely destroyed by fire on April 5. The building was equipped with numerous laboratories containing much expensive apparatus, and the loss is estimated at $750,000. The cause of the fire has not been determined.

Porto Rico Tuberculosis Sanatorium.—The San Juan Tuberculosis Sanatorium, the establishment of which is due to the exertions of the Anti-Tuberculosis League of Porto Rico, was dedicated on April 5 by Governor Winthrop. The league, which raised the money necessary to carry out the project was organized in March of last year. The municipality of San Juan appropriated $2,000 for the purchase of a site, and with this money twenty acres of high ground, overlooking the sea, near San Juan, was bought. The sanatorium was then erected with money raised by means of entertainments and private subscriptions. The insular government will contribute $300 a month and the city of San Juan $200 a month toward its maintenance, besides which a number of private donations have been promised.

Lord Lister's Birthday.—Lord Lister on April 5 celebrated his eightieth birthday and was the recipient of an immense number of messages of congratulation from all over the world. This is also almost the fortieth anniversary of antisepsis, for the first of Lister's publications on the subject appeared in the *Lancet* of March 16, 1867, with the title: "On a New Method of Treating Compound Fracture, Abscess, etc. Observations on the Conditions of Suppuration. By Joseph Lister, Esq., F. R. S., Professor of Surgery in the University of Glasgow."

Christian Science in Delaware.—Governor Lea of Delaware has signed the bill directed against the practice of Christian Science in that State. The new law prohibits healers of this sect from giving treatment for any compensation, gift, or reward. State Senator Dr. Thomas C. Moore of Smyrna was largely instrumental in securing the passage of the bill.

Nicotine-free Tobacco.—Numerous so-called nicotine-free brands of tobacco have been offered for sale from time to time, but these products do not seem to have become very popular. Now the French government, which controls as a monopoly the manufacture of tobacco in France, has put on the market a variety of caporal, the tobacco most used, said to have been deprived of its nicotine. To strengthen this assertion, it is stated that whereas rabbits into whose ear veins infusion of ordinary caporal was repeatedly injected, developed the lesions in the aorta resembling arteriosclerosis which have already been studied by experimenters, other rabbits treated in the same way with the nicotineless tobacco remained alive for months, and when killed were found to have healthy aortas.

Meningitis.—Cerebrospinal meningitis is beginning to appear again in some of the Prussian provinces and in Poland.

Foreign Physicians in France.—The regulations governing the practice of medicine by foreigners in France have recently been modified so that conditions are made easier for alien practitioners. From now on, physicians and students of medicine who have qualified for the final examinations in their own countries, if they intend to become naturalized, will be accorded the French degree of Doctor of Medicine on passing not more than three examinations, provided that they already possess the bachelor's degree or one equivalent to it.

Smallpox in Africa.—It is reported that smallpox has become epidemic in the German possessions in Kameroon, and the health authorities are making an effort to vaccinate the entire native and foreign population.

Industrial Dusts.—The American Institute of Social Service has received from Dr. Sommerfeld of Berlin a valuable antituberculosis exhibit for the department of industrial hygiene in its Museum of Security. There are forty-five specimens of different kinds of dust, mineral, animal, and vegetable, produced in various industries, and likely to be inhaled by workmen. The same number of photographs show the microscopical characteristics of these various dusts. Models in wax represent human lungs as they are affected by occupational dusts; other models show normal lungs for comparison, while still others show the effects of industrial poisons on the system. An advisory committee of the editors of the great technical papers has been organized to cooperate with the Institute in the work of protecting life and limb in industrial workers.

Race Suicide in Germany.—The statistics of the German Imperial Census Bureau relating to the births and deaths of the year 1904, which have just been published, show that the fecundity of married couples, which up to the year 1903 had been gradually declining, was slowly rising again.

The City of Düsseldorf, Germany, has granted a building site on which a local organization of women is to erect a building to serve as a training school for nurses in which young women from any part of the empire will be given free instruction in nursing.

Gift to Syracuse Hospital.—Mrs. Russell Sage has presented $5,000 to the Woman's Auxiliary of the Hospital of the Good Shepherd of Syracuse, N. Y., toward the $10,000 endowment fund for a free bed in that institution.

Bequests to Charities and Hospitals.—The will of the late William C. Egleston of this city, who died on March 25, filed for probate last week, contains charitable and educational bequests amounting to $275,000, of which Yale University and St. Luke's Hospital will each receive $100,000. The bequest to St. Luke's Hospital is to be used in endowing as many free beds, both adult and children's, as possible, these to be known as the "William C. and Ella Egleston beds," in memory of the testator and his wife. The other charitable bequests include $20,000 to the Sisterhood of St. Mary's Society of this city, to be devoted to the uses of St. Mary's Free Hospital for Children, in memory of the dead children of the testator, Louise and Adelaide Egleston. The New York Institution for the Blind will receive $15,000 under the will, and the New York Institution for the Instruction of the Deaf and Dumb $15,000.

Daniel Sheehan, who died in St. Vincent's Hospital on March 20 last, leaves $500 each to Sister Benign of St. Vincent's Hospital, to the Superior of the Little Sisters of the Poor of New York, to the Superior of the House of the Good Shepherd, to the Superior of the House of the Holy Family, to the president of the Mission of the Immaculate Virgin, to the Superior of St. Joseph's Hospital, the Bronx; to the Superior of the Foundling Hospital, East Sixty-eighth street; to the Mother Superior of the Dominican Convent of Our Lady of the Rosary, and to the Superior of the Catholic Hospital for Consumptives at Spuyten Duyvil.

Mount of Olives Hospital.—The foundation stone of the new German hospital on the Mount of Olives was laid April 1 in the presence of the Governor of Jerusalem, the other local officials, and many spectators. The land was given by Emperor William, and he was officially represented at the ceremonies.

Iowa City Homeopathic Society.—On March 28 this Society was organized and Dr. Leora Johnson elected president and Dr. T. R. Hazard secretary.

Boston Society of Examining Physicians and Surgeons.—At a meeting held on April 3 this Society was organized and officers were elected as follows: *President*, Dr. Francis D. Donoghue; *First Vice-President*, Dr. Frank E. Allard; *Second Vice-President*, Dr. Edward M. Greene; *Secretary*, Dr. Charles T. Cutting; *Treasurer*, Dr. Charles O. Kepler. There will be three meetings a year, and all physicians and surgeons in good standing who examine regularly for some association or corporation are eligible for membership.

Hardin County (Ia.) Medical Association.—At its annual meeting held in Eldora on March 29 the following officers were elected for the ensuing year: *President*, Dr. J. J. Miller of Ackley; *Vice-President*, Dr. C. O. Mabie of New Providence; *Secretary*, Dr. W. E. Whitney of Eldora; *Treasurer*, Dr. R. Thornton of Ackley.

For a Dutton Memorial.—A movement is on foot in England to collect a fund of $50,000 to endow a Dutton Memorial Research Professorship in tropical diseases in honor of Dr. Joseph Everett Dutton, the discoverer of the *Trypanosoma gambiense*. He died of tick fever in Kasongo at the age of twenty-nine years, while a member of a commission investigating this disease.

The Graduate Medical School of Cincinnati opens for the first time this spring. The teaching force is the faculty of the Medical College of Ohio, the Medical Department of the University of Cincinnati, with which it is connected.

The Late Dr. George Bingham Fowler.—At the stated meeting of the Medical Society of the County of New York, held Monday, March 25, 1907, the following preamble and resolution was unanimously adopted: *Whereas*, Death has removed from us one of our ex-presidents, Dr. George Bingham Fowler, a distinguished and respected member of this Society; therefore, be it *Resolved*, That we deeply regret the loss we have sustained, not only in our individual relations to him, but also in the various public and consulting positions which he held, and be it further *Resolved*, That we extend our deepest sympathy to the bereaved family of the deceased, and that a copy of these resolutions be spread in full upon the minutes of the Society and be published in the medical papers. (Signed) Wendell C. Phillips, Edward D. Fisher, Charles N. Dowd, Committee.

Obituary Notes.—Dr. M. A. Sheffield of St. John, N. B., died suddenly of heart disease on March 30. He was born in Cornwallis, N. S., in 1837, and received his medical education in the Bellevue Hospital Medical School. For five years he practised in Berwick, but in 1872 removed to St. John, where he had since resided.

Dr. J. N. Knight of Cliftondale, Mass., died on March 30 after an illness of about a year's duration. He was born in Salem in 1862, and was graduated from the medical department of Boston University in 1883. Shortly after graduating he settled in Cliftondale, and had practised there ever since.

Dr. William D. McCarthy of San Francisco, Cal., died on March 14 after a long illness consequent on service in the Philippines during the Spanish-American War. Dr. McCarthy was born in Boston in 1861, and, after receiving his preliminary education in St. Mary's College, was graduated from Cooper Medical College in the class of 1885. At the opening of the Spanish-American War he enlisted in the First California Volunteers, and served as surgeon in the Philippines until the regiment was recalled two years later.

Dr. Edward L. Carpenter of Louisville, Ky., died on March 24, at the age of forty-one years. He was the son of the late Dr. L. M. Carpenter of Louisville, and received his medical education in the University of Louisville.

Dr. Albert M. Warner of Waukesha, Wis., died on March 16, at the age of ninety-one years. He was born at Andover, Vt., and was graduated from the Vermont Medical College at Woodstock in 1842. After practising for a time in New York State, he removed to Waukesha in 1845, and had resided there until about three years ago, when he went to live with a daughter in Chicago.

Dr. A. C. Simonton of Seattle, Wash., died on March 27, at the age of sixty-five years, after a long illness. He had practised for many years in Des Moines, Ia., but eight years ago removed to Roslyn, where he was one of the surgeons at the Northern Pacific mines.

Dr. Charles Francis Reilly of Woonsocket, Mass., died on March 31 of heart disease. He was born in Blackstone in 1872, and received his medical degree from the College of Physicians and Surgeons in Baltimore in the class of 1902. After his gradua-

tion he practised for a time in Everett, Mass., and Millville. About a year ago he removed to Woonsocket.

Dr. Harry E. Burdett of St. Paul, Minn., died of heart disease on March 28 at the age of forty-five years. He was a native of Belleville, Ont., but had practised in St. Paul for over twenty years.

Dr. J. N. Taylor of Lynchburg, Tenn., died suddenly on March 29, at the age of seventy years. He had served with distinction in the Confederate Army and had practised for over thirty years in Lynchburg.

Dr. John M. Winfree of Richmond, Va., died on March 31 at Raleigh, N. C., after a long illness. He was graduated from the Medical College of Virginia some years ago, and at once began to practise in Richmond, but in 1905 was obliged to give up active work on account of ill health.

Dr. J. P. Crawford of Davenport, Ia., died on March 25, at the age of fifty-one years. He was prominent in medical circles, and was for many years surgeon for the Chicago, Milwaukee and St. Paul Railroad Company.

Dr. Clarence E. A. Buckley of Halifax, N. S., died on March 28, at the age of twenty-five years. He was a son of Dr. H. F. Buckley of Halifax, and was graduated from Dalhousie Medical School in 1904. He practised in Thorburn until about a year ago, when forced to give up active work on account of illness.

Dr. James S. O'Sullivan of Randolph, Mass., died on March 25 of pneumonia, at the age of forty-two years. He was a native of Worcester, graduating from Holy Cross College, and later from Harvard Medical School. He practised for a time in West Quincy, but for the past eight years had been a resident of Randolph.

Dr. Frank Swartzlander died at Doylestown, Pa., on March 31, at the age of sixty-four years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1863. During the Civil War he was assigned to the Military Hospital in Philadelphia, and later to the Seventy-fourth Pennsylvania Volunteers. At the battle of Gettysburg he was surgeon of the operating staff of the field hospital of the Eleventh Army Corps. Later he was assigned to join Sherman in his march to the sea, meeting the army at Savannah, where he was placed in charge of the auxiliary military hospital. He remained in the hospital service until the end of the war.

Dr. Ashbell P. Grinnell of this city died on April 6 after a long illness, the immediate cause of his death being septic endocarditis. Dr. Grinnell was graduated from the Bellevue Hospital Medical School in 1860, and was for years Dean of the Medical College of the University of Vermont. Of late years he had interested himself in forensic medicine, and at the time of his death he was vice-president of the Medico-Legal Society.

Dr. George R. Shepherd of Hartford, Conn., died on April 6, at the age of sixty-two years. He was graduated from Yale Medical School in 1866 and was Medical Director of the Connecticut Mutual Life Insurance Company.

Alcohol in Diabetes.—Benedikt and Török in the course of investigations on the rôle of the fats in the formation of the acetone bodies in diabetes studied the effect of alcohol in this disease. They found that on adding about three ounces a day of brandy to the dietary a marked diminution in the amount of acetone bodies resulted. They conclude that alcohol is useful because it reduces the sugar excretion and saves albumin.—*Zeitschrift f. klin. Medizin.*

Correspondence.

THE VENEREAL PERIL.

A POSSIBLE STEP TOWARD ITS REMOVAL.

To the Editor of the Medical Record:

Sir:—"For the safety of the public," is a cry often heard to-day, and truly much is being done in many directions for the betterment of conditions generally. The various boards of health throughout the country have accomplished a great deal by their vigorous fighting to lessen and keep down the spread of tuberculosis, and hope eventually to eliminate that dread disease entirely. The same boards have dealt admirably with many other forms of disease and conditions that have proved a menace to the public health, so that to-day we stand protected, or nearly so, from many of the commoner forms of contagion and infection. There is, however, one subject that has been overlooked, apparently, or possibly it has presented itself, or been presented for consideration, but because of its nature, which necessarily involves much deep thought and attention, it has been impossible for the several boards or commissions of public health to agree upon a suitable course to pursue, and which, in the meantime, has been allowed to run riot. The condition to which I refer is the venereal peril.

When we stop to consider the awful ravages that are continually presenting themselves as a result of infection from gonorrhea or syphilis, the thought—How can we prevent a furtherance of these conditions?—is very apt to arise. The profession is only too well acquainted with the existing state of affairs, but the laity, who know little or nothing of the nature or manner in which these dread diseases are spread—in fact, who are thoroughly ignorant of the awful suffering extant as a result of infection by one or the other condition—are the ones who should in some way be enlightened and thereby better protected. The parent who, because of a sense of what he or she may consider modesty, hesitates to speak to the budding youth or maid on a subject that seems too delicate and complex for the presumably tender and sensitive mind to grasp, is guilty of gross negligence and such neglect on the part of parents who are at all aware of the existence of present conditions is, in my mind, almost criminal. Often the parent hesitates to speak on the subject because of insufficient knowledge, and just here is where the public health commission can begin a most magnificent work. But little or no attention is given—certainly not the proper attention—and why? Is it because the subject, being of the nature that it is, is considered indecent and not fit for public discussion? Should modesty of speech be permitted to stand in the way of the safety of the public health? It is a duty that we (the profession) owe, as protectors of the health and well-being of the community, of the world at large, to see that proper means are taken to obliterate this appalling condition which now exists. Shall the younger generation and those to follow continue to become the innocent recipients of these frightful contaminations, and all simply because of the fact that the public is not sufficiently enlightened? Something must be done and that promptly or the untold sufferings will continue and increase until they shall have reached a stage where it will be almost impossible to offer relief.

If the young man or young woman arriving at a time or age when the sexual appetite begins to make demands on the mental proclivities for satisfaction, were sufficiently well informed and apprised of the possible dangers concomitant with a general disregard for virtue and morality, how much good would result. How many young women would be saved from the tortures of an infected uterus, pus tubes, and inflamed ovaries. How many infants would be spared the agonies of an ophthalmia or the sufferings that follow an inherited syphilis.

As a step toward obliterating all this I would suggest and recommend a graded system of lectures to be delivered to the children of our public schools and institutions as a part of the regular curriculum, beginning with children of an age or sufficiently advanced to understand the principles of contagion and infection. Pamphlets dealing with the subject could also be supplied by health officers to parents for home instruction. Special lectures could be arranged for older boys and girls and men and women, and still others for the unfortunates who have suffered and are now in the throes and who, learning of the enormity of the affair, would prove a factor in controlling the spread of the peril. Much can be done by the health boards in passing amendments to the law, compelling the removal from public use of the cigar cutter, drinking cup, etc., and also in

insisting that all restaurants and hotels, even the inferior ones, of course, boil and properly disinfect all towels, linen, napkins, etc., in public use.

The subject, you will admit, is an all-important one and worthy of serious consideration. Much more can, and doubtless will, be said on the subject, but the time is now ripe, and quick and strong action should be taken in an effort to crush this death-dealing monster that pollutes the race.

THE FRESH AIR TREATMENT OF PNEUMONIA.

To the Editor of the Medical Record:

Sir:—Our medical papers are of late advocating a new treatment of pneumonia, namely, the fresh or cold air treatment, representing this treatment as a rather new way of dealing with this disease. In this case, as in a good many others, history repeats itself.

I cite Juergensen in Ziemssen's Handbook of Special Pathology and Therapeutics, Leipsic, 1877, page 174, translated from the German edition: "A pneumonic patient above all needs fresh air. If we can procure air without producing a draught, so much the better; but if we have to choose between foul air and draught, let us choose the draught and our patients will do well. Even if we let them take a bath under these conditions, and their wet skin is exposed to the draught, there is no danger. Very often we have removed a pane of glass from a window, or even the whole window, to let in fresh air, and we never have observed complications, such as bronchitis, pleurisy, and pericarditis; and we have never noticed a bad effect in the sequelæ of pneumonia, such as chronic pneumonia, phthisis, and so on. We would therefore not hesitate to expose our patients to the air until the temperature goes down, if we thought that the temperature should be reduced and cold baths could not be used."

Juergensen, by the way, also recommends cold baths for the treatment of pneumonia.

Arthur Stern, M.D.
Elizabeth, N. J.

ESPERANTO.

To the Editor of the Medical Record:

Sir:—Your remarks in the Medical Record of March 30 relating to the pronunciation of Esperanto are apt to be misunderstood and so create the impression as though Esperanto were pronounced so diversely by the different nations that they hardly understand one another. I would ask you, therefore, to allow me space in your valuable paper for a reply obviating this impression. There is no natural language which is pronounced precisely alike everywhere in its own country. The university professor born in Leipzig pronounces the German differently from the professor born in Berlin, the latter differently from the one born in Munich. The English of a Bostonian college graduate sounds differently from the English of a New York college graduate. Something similar is true of the French language, etc. Now let me tell your readers that the differences in pronunciation of Esperanto are much slighter than those met with in any living natural language. I can make this assertion from my own experience and investigations, as well as from the facts brought out at the two international congresses of Esperantists. At the Boulogne congress in August-September, 1905, 1,200 delegates from twenty-two different countries were assembled. Many of them spoke Esperanto without the slightest difficulty in understanding one another. At the second congress in Geneva in August-September, 1906, twenty-three countries were represented. Many of the delegates of different nationalities conversed in the new language so freely and easily and with such fluency and even loquacity that the uninitiated gained the impression they were speaking their mother tongue. Differences in pronunciation noticeable at the first congress to the trained ear of the student of the subject of pronunciation were much less noticeable at the second congress.

Just because the pronunciation of Esperanto is extremely simple, the first manuals of the language paid little attention to it, and were rather careless in its exposition. Noticing this, I made careful observations of the existing differences and investigated specially the pronunciation by discussion with a European Esperantist living in the United States, but having learned the language in Europe, and who had known and spoken with its inventor; further, by extensive correspondence with the most prominent European Esperanto authorities, including the ingenious creator of Esperanto, Dr. L. Zormenhof. The result of my investigations is laid down in my text book.

Up to the present time Dr. Zamenhof is the recognized incontestible, official authority in everything pertaining to Esperanto, and no author of a text book has contradicted him in matters about which he was explicit. Neither am I at variance with the illustrious inventor of the new language. The passage in my book which seemed to you to contradict Dr. Zamenhof on the contrary shows expressly that he teaches the same pronunciation of a certain diphthong as I do, only that the inference which he, in one of his letters to me, made from this pronunciation was "unintelligible" to me.

The differences in the pronunciation of Esperanto are gradually disappearing, since the Esperanto authorities have begun to pay more attention to pronunciation. But even if they were never to disappear, they are, as stated above, of such a slight degree that they would never disparage the language or even cause it to undergo the same fate as Volapük.

Dr. Max Talmey.

OUR LONDON LETTER.

(From Our Special Correspondent.)

INSANITY—CHYLURIA—KING EDWARD'S HOSPITAL FUND—INCORPORATION OF KING'S COLLEGE WITH UNIVERSITY—OBITUARY.

London, March 22, 1907.

Insanity has been prominently before the profession and the public during the last few days. The most important contribution to the subject is the course of Lumleian lectures at the Royal College of Physicians by Dr. Geo. H. Savage. He opened with a naive confession of pride at his selection, followed by doubt about his subject, and then a dread of failure. But his life's work indicated to him something connected with insanity and though the field had been partly occupied he happily decided that he might add something from his own special experience. He has thus given us interesting food for thought. Admitting a considerable increase of the insane, he has no dread of the future of the race and he endeavored to show that much insanity does not depend on material brain disease, but has reference to the complexity of society and the numerous social misfits which occur, many persons being treated as insane because they are out of harmony with their surroundings. He proposed no fresh classification, holding with Hughlings Jackson that alienists are more like market gardeners than botanists—have groups for convenience, but no natural orders. Unsoundness of mind often occurred without anything that could be called insanity arising. The medical man looked for brain change, the lawyer for responsibility, society considered only whether a person was a danger to himself or others. There could, therefore, be no common pathological basis for the various classes, and the lecturer maintained that there are many cases in which there is no ground for suspecting any material change in the nervous system. Insanity was not a definite disease, but a negation. There was no fixed standard of sanity, and insanity was often a question of degree. Normal feelings might pass into delusions, and Dr. Savage did not expect to find a seat in the brain for such ideas. He accepted what Hughlings Jackson had written in his "Factors of Insanity" as to the removal of the higher spheres of control and letting loose the lower. Referring then to some typical forms, the lecturer said we may have mental disorder marked chiefly by loss of this higher control, varying in degree from hysteria to acute mania; parallel to this, delirium from toxic agents may be noted, showing hallucinations of the senses. Melancholia ranges from hypochondriacal self-consciousness to profound stupor. This seems increasing, as does dementia, general paralysis, and senile disorders. Dr. Savage believes there is an increase among the simply neurotic, that neurasthenia is also on the increase, and such conditions are at the root of a large number of cases of delusional insanity, chronic recurrent insanity, and paranoiac insanity, which fill our asylums.

In his second lecture Dr. Savage dealt with heredity, combating the common idea that insanity of all forms was inherited. Consanguineous marriages were not dangerous from merely near kinship and the old idea that the deaf and dumb or weak minded owed their infirmity to marriages of cousins had not been confirmed. There was indeed a tolerably definite neurotic stock or type, but in

his opinion insanity as such was not transmitted. Still, in the insane there was a strong tendency to produce offspring who were unduly unstable. But insanity, like genius and all highly specialized mental capacities, tended to extinction or to nervous instability in the following generations. Great inventors, millionaires, and persons of exceptional genius all ran a great risk of having degenerate children. The general tendency of highly gifted parents was either to have no children or to have neurotic offspring. So said Dr. Savage, but the impressions left by reading many biographies seems a different one, though of course such impressions are not to be trusted. The lecturer next remarked that tricks or habits often reappeared in children—even the handwriting of children frequently resembled that of their parents, though here again I might interpolate a doubt as to the cause assigned, for a child often learned from its father or mother, or if not so taught might delight in imitating a parent's rather than a tutor's writing. This imitative disposition seemed to be recognized, if unconsciously, in Dr. Savage's next point, the great danger of association of an insane parent with a child. He had known children living with an insane parent to develop the same or similar delusions. The insane or highly neurotic parent tended to pass on, if anything, special forms of insanity, which might be called habit insanities and a tendency to break down at certain epochs of life, making them incapable of bearing normal physiological stress. But with that there was an extraordinary power of recovery, so that patients of a highly neurotic stock might have dozens of attacks of violent mania and retain till the end of a long life mental ability. The conclusion was that there was no such thing as transmission of any form of insanity direct, but there was a danger of the passing on of a nervous instability which led to mental disorder resulting from slight or even normal physiological strain.

On Tuesday a paper was read at the Royal Statistical Society by Mr. Noel A. Humphreys, dealing with the "alleged increase of insanity." In his opinion no proof whatever had been advanced of such increase. He pointed out the fallacy of regarding the number of certified and registered cases as a proof of increasing prevalence. There was a reserve of mental unsoundness outside the control of the lunacy commissioners, though that had been declining of late owing to greater accuracy of registration and changes in the degree of insanity for which asylum treatment was deemed desirable. Moreover, people appreciated the improvement effected by asylum treatment and were less desirous of resuming personal care of discharged cases. There had been a constant decline of the discharge rate (including deaths), accounting for the accumulation of cases in the asylums. Mr. Humphreys demanded a scientific definition of what constituted insanity as a necessary preliminary to a solution of the question whether the prevalence has increased or decreased.

On Tuesday Mr. Gladstone (Home Secretary) received a deputation from the Lancashire authorities on asylums and the poor law to urge more economical housing of chronic lunatics. He replied to the deputation that he understood the general view of experts to favor a higher standard of medical treatment, diet, housing, etc., for curable cases. Of course special effort was desirable whenever there was a chance of a cure, and he was sure that all reasonable and proper care would be given to others. He therefore considered differential treatment was absolutely justifiable and would cooperate with the deputation in that object.

A case of chyluria in England was described by Dr. A. F. Hertz at the Medico-Chirurgical in a sailor of 66, admitted in October, 1906, with a history of milky urine for about nine months. He had been in India twenty years previously. The opacity was due to fat; proteid was always found, dextrose never. The fat and proteid disappeared with a fat-free diet if he rested after meals. But fat in food gave rise to proteid and fat in the urine as soon as thirty-three minutes—the maximum amount being about five hours later, and the last traces about eight hours. Exercise or the upright position increased the amount. At the post mortem the thoracic duct was obstructed about 7 c.m. above the diaphragm. The abdominal lymphatics were dilated and there was an anastomosis between the lacteals and the lymphatics on the right side of the bladder, inside which fibrin adhered to the mucous membrane at a point where dilated lymphatics were, and which perhaps marked the spot where the contents of the lacteals and lymphatics of the leg had penetrated. It was suggested that the case might be due to an old infection by filariæ which had died out but left the obstruction brought on. Non-filiarial cases might be due to another parasite or to pressure on the duct by a tumor, the most frequent being caseous glands.

The annual meeting of King Edward's Hospital Fund was held this day week, the Prince of Wales as president occupying the chair. The report stated that the total income had amounted to £110,955 and the sum distributed to £111,000. Donations and subscriptions showed a decrease of over £13,900. Of this, £10,000 represents the loss of the generous subscription of the late Mrs. Lewis-Hill, but by her death the fund comes into the capital sum of £250,000, besides a residue of the estate not yet ascertained. Legacies are acknowledged from Mr. Beit, £20,000; Mr. Nicholas, £10,000; Lord Grimthorpe, £5,000, and Mrs. Finnie's estate, £6,700. The League of Mercy contributed £18,000, an advance of £3,000 on the previous year. Every eligible hospital applying to the fund for a grant was inspected and reported upon and the council expressed pleasure at noticing a diminution of expenditure in several hospitals in which the cost per bed seemed to have been excessive. The revision of the uniform system of hospital accounts was brought to a successful conclusion during the year 1906; the three funds have adopted the system which is now in force. Last year H.R.H. the president appointed a finance committee in view of the magnitude of the fund's invested property. He also expressed a desire to place the fund on a defined footing, by incorporation by an act of Parliament. With the approval of the King, steps are being taken to seek the consent of Parliament to a bill for accomplishing that purpose.

King's College issued its appeal on Saturday for funds to carry out its incorporation in the University of London. One hundred and twenty-five thousand pounds is required and an additional £20,000 to keep up the theological faculty, for this is necessarily separated and independent on account of the undenominational character of the university. The council point out that during the last ten years they have made great efforts to improve the college, have reduced the debt by £56,000, and secured £14,000 for the extension and equipment—most of this being provided by private friends. They, therefore, think they may now reasonably ask institutions and individuals interested in higher education in London to help them complete the work. The debt began with the opening of the college seventy-five years ago and has grown with the effort to meet the requirements. The scheme of incorporation follows on the lines of that of University College. This, however, was undenominational, and therefore it is only the secular side of King's that will be completely incorporated. The faculties of Arts, Law, Science, Engineering, Medicine (preliminary and intermediate) and the women's department at Kensington will be continued and governed by the Senate through a committee or delegacy. The hospital and advanced medical school has to be under separate management and is transferred to the new suburban premises toward the building on which £170,000 has been collected and much more is required. The separation facilitates the incoporation, as the university cannot be connected with the management of a hospital, nor can it be responsible for one of the twelve advanced medical schools of London.

Surgeon-General Sir John Harry Innes, K.C.B., died at Florence on the 12th inst., aged 87. He graduated in 1842 and entered the Army Medical Department. He served in the Crimea, through the Indian meeting and later in Afghanistan; was Sanitary Commissioner in the Franco-Prussian war, 1870, and P.M.O. in India from 1876 to 1880. He was appointed Surgeon to Queen Victoria in 1872 and created K.C.B. in 1887.

Dr. Samuel Barker, Consulting Physician to the Children's Hospital at Brighton, and one of its founders, died on the 11th inst., aged 86. He was M.D., St. And., 1858, and had retired for many years. He held some other appointments at Brighton, where he had practised for about fifty years and had the respect of all classes. He made a number of contributions to medical literature, chiefly on subjects connected with the health and diseases of children.

Facial Neuralgia and Radiotherapy.—Béclère and Harrey have reported a case of facial neuralgia in which the pain disappeared after a course of radiotherapy. The patient was attacked seven years ago with an epileptiform facial neuralgia. Several surgical interventions were performed, but were followed by a subsidence of a violent pain for only a few months. Finally recourse was had to radiotherapy. This treatment resulted in the complete disappearance of the pain after four sittings eight days apart. The rays were directed toward the interior of the mouth against the alveolar border. The neuralgia has not returned since April 25, 1905.—*La Tribune Médicale.*

(From Our Special Correspondent.)

ANNIVERSARY CELEBRATIONS—INCREASE OF MEDICAL FEES—TUBERCLES OF THE LIVER—SUBCUTANEOUS USE OF GELATIN IN CARCINOMA—LEUKEMIA WITHOUT LEUCOCYTOSIS—AN OPERATION FOR CLEFT PALATE—MORTALITY FROM TUBERCULOSIS AND CANCER.

VIENNA, March 20, 1907.

On March 16 the Royal Institute of Operative Surgery celebrated its centenary. This institution has as one of its functions the education of surgical assistants who later enter the clinics in order to perfect themselves by several years' work under the tutelage of eminent specialists. Many prominent operators have received a portion of their training in the Institute; in fact, nearly all the surgeons of the Austrian clinics of the last decades excepting Prof. Billroth, who himself during his work in Vienna was director of the Institute. A large number of well known foreign surgeons have also been workers in the Institute. Receptions were held in the two university clinics, in conjunction with which interesting cases were presented and the clinics were inspected. At the first clinic the guests were received by Councilor von Eiselsberg, who in a short address outlined the revolution in surgery that had been effected by the development of anesthesia and of antisepsis. He referred to the approaching eightieth birthday of Lord Lister and said that the great English surgeon must today be experiencing the delightful conviction that thanks to his discovery millions of lives had been saved that otherwise would have been lost. Prof. von Eiselsberg then referred to the operation of appendectomy, which he termed the most modern of operations, and he presented a statistical table of 700 cases intended to show its value. The assemblage then passed on into the second surgical clinic, where Councilor Hochenegg spoke on the increase in the scope of operative surgery during the last fifty years. In the year 1841 in this clinic 56 major operations were performed, in the year 1867 120, in 1887 512, and in 1896 713. In the year 1869 no case of appendicitis came to operation, in 1899 there were 14 cases, and in 1896 128 cases. The number of gallstone operations in 1899 was 2 and in 1906 was 20. The speaker then presented several patients who had recovered after unusual surgical conditions. A collation given by the chiefs of the two surgical clinics formed the conclusion of the exercises.

All of the participants in this centenary celebration, on the evening of the same day took part in a testimonial meeting held in the assembly room of the medical society in honor of Lister's eightieth birthday. The meeting was presided over by Councilor Chrobak and the address was delivered by Prof. Fraenkel. He said that two considerations rendered the present celebration a solemn one, one of them was the retrospect over the hundred years of activity of the surgical Institute and the other was the entrance of Joseph Lister, the great reformer of surgery, into the ninth decade of his illustrious life. After pointing out the true altruism that pervades the medical profession in its labors for the good of the populace, he closed with the quotation from the Roman Emperor who said, "Melius est unum servare civem quam mille occidere hostes."

To conclude the centenary celebration the chiefs of the university clinics, Profs. von Eiselsberg and Hochenegg, had invited the guests to a reception in the university. At 9 o'clock in the evening almost all the professors, instructors, and assistants of the medical faculty, prominent members of the three other faculties, as well as a large number of eminent physicians and former graduates of the Institute from all countries assembled in the reception rooms. The dean of the university and his suite entered the hall in solemn procession. From the rostrum, beside which the banner of the university had been planted, the rector delivered an address of welcome. He expressed his pleasure at seeing all the members of the medical school united again in the university, since the separate medical institutes were situated outside of it, and emphasized the value of the spirit of unity conferred by the university. Dr. Scholz then delivered an address of thanks to the academic senate in the name of those who had enjoyed its hospitality. Hereupon the guests formed informal groups in the adjoining rooms in which the supper tables had been placed, and old classmates who had not seen each other for years celebrated their reunion.

All through Austria-Hungary there has been of late such an increase in the cost of living that even the physicians have decided not to hold back any longer and have concluded to increase their fees by 50 per cent. Many circumstances have of late years contributed to cause a diminution in the prosperity of the medical profession, especially overcrowding of the profession, the reduction in fees caused by the lodges, and the foundation of charitable institutions on a large scale by wealthy persons, so that an effort to increase the income of the physician seems fully justified.

Dr. Schnitzler has removed by operation large solitary tubercles of the liver from a young man. The patient, who several years before had been operated on for tuberculous glands of the neck, two years ago began to complain of pain in the region of the liver. The organ was enlarged and on palpation was found to be nodular. Antisyphilitic treatment, founded on a diagnosis of hepatic gummata, was without effect. At an exploratory laparotomy it was seen that the right lobe of the liver contained numerous white, hard tumors resembling gummata in appearance. After the operation a temporary diminution in the pain and in the size of the tumors was noted, but as the improvement was not of long duration laparotomy was performed. From both lobes of the liver a number of hard tumors, some of them almost as large as the fist, were removed: hemorrhage from the incisions into the liver was controlled by packing with adrenalin tampons. On microscopical examination it was found that the tumors were tubercles, the occurrence of which in such size is a great rarity. At present the patient's condition is excellent.

Hauer has made numerous observations on the subcutaneous administration of gelatin in carcinoma, and in the course of the past two years has frequently resorted to injections of a 10 per cent. solution of this substance in the treatment of hemorrhage due to carcinoma of the uterus. The general condition of these patients improved greatly, and in some instances the cancerous process itself was changed for the better. In order to investigate the matter further, observations were made in thirty-eight cases of carcinoma and two of sarcoma. The hemorrhages in most cases ceased after one or two injections and the greater proportion of the patients showed a considerable increase in weight. The pain diminished, the general condition improved, the cachexia was lessened and the mucous membranes regained their color: the odor of the discharges became much less offensive and in some cases the growth itself gave evidence of retrogression. The ulcers became less purulent, their size diminished and in some of the cases clinical changes were observed that appeared to justify the opinion that the primary lesion had been cured. The metastases were less favorably affected, though here also the process was arrested. Gelatin is to be considered as the best palliative remedy in carcinoma, and in inoperable cases is a most useful means of alleviating symptoms. The injections of 40 g. each are given at intervals of one or two weeks for months. To explain the action it is supposed that cytolysins are formed in the body, or that the gelatin causes thrombus formation in the arterioles of the new growth.

A case of leukemia without leucocytosis has been observed by Sluka in a nine-year-old girl. The diagnosis of acute lymphatic leukemia was suggested by the general symptom complex, consisting of pallor, puffiness of the face, general glandular enlargement, cutaneous hemorrhages, and the rapid onset of the condition. The blood picture caused astonishment, therefore, for it presented a leucopenia with a predominance of the lymphocytic elements, which were of the type common in acute lymphatic leukemia. Apparently the number alone of the white cells is not to be considered in the diagnosis of acute lymphatic leukemia, but the most important feature is their morphology. According to Türk, such cases should be termed acute alymphemic lymphomatosis. The prognosis is bad, for in all the cases so far observed death has resulted in less than a year, usually in four to six months. Roentgen ray treatment would hardly be indicated in such a case, since it would not be desirable to decrease still further the small number of leucocytes present.

Moszkowicz has operated on fourteen children with congenital cleft palate by a method that was suggested as long ago as 1824, but which has since fallen into disuse. It consists in the formation of a flap of mucous membrane and periosteum on one side of the defect, which is freed by two incisions running parallel to the cleft and to the alveolar process, and is then stripped up from the bone. The opposite edge of the cleft is freshened and the border of the flap is sutured to this so that it covers the gap. According to this method, it is possible to close wide defects and if necessary a second flap may be formed from the other side. By prolonging the flap backward the defect in the soft palate is closed in a similar way. Two cases which were operated on while only a few days old ended fatally, and it therefore appears to be advisable at first to correct only the harelip and to close

the opening in the palate by means of an obturator. Later on, but before the children begin to speak, the staphylorrhaphy is done. In the other twelve cases the functional result was very good. By injecting adrenalin it was found possible to control the hemorrhage perfectly.

The municipal authorities of Vienna have issued some interesting statistics relating to the mortality from tuberculosis and cancer in the year 1904. Pulmonary tuberculosis forms 17 per cent. of the causes of death, but in the last fourteen years has been diminishing steadily. All ages are attacked, but it is commonest in persons of the productive time of life, from twenty to thirty years of age, and more men than women succumb. Persons in the humbler walks of life suffer more from tuberculosis than those in better circumstances. A somewhat different state of affairs prevails in regard to carcinoma and other malignant new growths. Here the mortality is greatest among those of advanced years, and women predominate. Cancer also is rather a disease of the better classes.

Progress of Medical Science.

New York Medical Journal, March 30, 1907.

Hodgkin's Disease as a Type of Sarcoma.—After a reference to the histological changes in and symptoms of this affection, W. B. Coley presents illustrations of several personal cases together with their clinical histories. He states his conviction based on a study of upward of 600 cases of sarcoma, 74 of which originated in the cervical glands, that Hodgkin's disease is merely a special variety of sarcoma, in containing as a rule a fairly definite clinical and pathological type, but yet, in many cases, shading off into other types that correspond most closely with the ordinary types of round celled sarcoma. The very evidence brought forward by Reed and others in favor of the infectious origin of Hodgkin's disease need not be disproved. Most of it holds true of sarcoma, and all of it but adds to the slowly accumulating mass of evidence in favor of the microparasitic or infectious nature of sarcoma as well as carcinoma. The question of retaining the name Hodgkin's disease is not of great importance compared with the recognition of the true pathological condition, just as it matters little whether we call a certain disease of the thyroid gland exophthalmic goiter or Graves' disease. If the malignant nature of the disease becomes generally accepted, as the author believes it undoubtedly will, it will be hard, he thinks, to find a better name for the disease than lymphosarcoma, which Billroth applied to it many years ago, prefixing multiple to it; or calling it lymphosarcomatosis to distinguish it from the type of sarcoma confined to a single lymph gland.

The Possible Significance of the New Pyloric and Duodenal Lesion Observed in Guinea Pigs Inoculated Subcutaneously with Diphtheria Toxin.—The lesion referred to by W. D. Cannon consists of sharply defined areas of congestion, hemorrhage, or ulceration involving the pyloric end of the stomach and sometimes the duodenum to the extent of half an inch. He refers to the work of Turck, Rosenau, and Anderson who first observed the above change, and calls attention to the possible significance of such lesions in the general study of the induction of artificial gastric ulcer. The author further brings up their possible relation to the familiar duodenal ulcer occurring in the human subject after superficial burns of large skin areas. He asks, does not the intense acute inflammation of the subcutaneous connective tissue in the guinea pig, with its resultant hyperplasia, edema, and sometimes necrosis of the skin, involving from 64 to 100 c.c. of dermal tissue surrounding the site of inoculation, constitute a skin lesion analogous to skin burns of the first or second degree? There is probably impairment if not total arrest of the skin functions, absorption, excretion, respiration, heat radiation, sensation, and protection in the area involved. Just which one, or combination of arrested functions, is capable in inducing duodenal ulcer, and later weath, has not been determined.

Pubiotomy.—R. C. Norris notes the growing popularity of pubiotomy over symphyseotomy, and reports one successful case. The degree of pelvic deformity indicating pubiotomy is the same as that ordinarily given for the relative indication of cesarean section, *i.e.* a conjugata vera to 7 c.m. The majority of operations thus far have been done for cases with contraction between 7 and 8.5 c.m. To replace embryotomy it has also been recommended and performed in cases of impacted face or brow presentation. It has been recommended to place the saw ready for section of the bone as a prophylactic measure when about to extract a difficult breech presentation or after version. The increase in the diameters is as follows: A separation of the cut ends of the bone of 3 c.m. increased the conjugata vera 1 c.m.; the transverse 1.4 c.m.; both oblique diameters 1.3 c.m. A separation of 4 c.m. is likely to damage the sacroiliac joint. One authority declares the conjugata vera in the normal pelvis is increased 8 per cent. of its length; in the rhachitic pelvis over 25 per cent. The space gained is about the same as is gained with symphyseotomy with equal separation of the bones. The advantage of pubiotomy lies in the fact that the supports of the bladder and urethra and the clitoris and structures behind the symphysis are not only not cut, but also are not so likely to be lacerated by the bilateral traction caused by the separation of the bones. Lacerations of the vagina and unavoidable hematomata have been the most frequent accidents thus far reported. Under aseptic conditions these really are not serious and often may be avoided by a proper technique of operation and by a proper method of delivery. Tearing of the vaginal or cervical attachments ought to be avoided by careful delivery after section of the bone. Reference is made to the literature on the subject and noteworthy incidents in various cases reported by the different authors are also referred to.

What Stage in the Development of Cataract, Particularly Senile Cataract, Is the Most Suitable for Its Removal by Extraction?—J. E. Weeks briefly describes the most frequent types of senile cataract. These are: (1) Equatorial (cortical) cataract: (a) imbibition cataract; (b) cataract, always smaller than the normal lens. (2) Cortical (chorioidal) cataract; anterior, or posterior, or both. (3) Nuclear cataract. He adds that extraction of the cataract in the foregoing types described, if done when most propitious for the welfare of the patient, would be performed in the *first type* as soon as liquor Morgagni appeared between the lens capsule and the lens substance; in the *second type*, at the convenience of the patient after vision is reduced below that necessary for the ordinary vocations of life; in the *third type*, when useful vision has been abolished, and the lens is appreciably shrunken. The author also refers to the zonular type where the cataractous portion becomes so dense and is so large that vision is reduced below the point which enables the patient to follow the ordinary vocations of life (particularly when the density of the cataract reaches this stage in adults) and the cases in which calcareous deposits render dissipation of the cataract by needling imprudent or impossible. Extraction in this fourth type should be made at the convenience of the patient after vision is reduced below that necessary for ordinary uses.

Journal of the American Medical Association, April 6, 1907.

Tuberculous Meningitis.—H. Koplik gives an analysis of fifty-two cases of tuberculous meningitis occurring in his hospital practice during the last six years. All the cases utilized in his article were diagnosed clinically and the diagnosis confirmed by post mortem, lumbar puncture, or animal experimentation. The oldest patient was ten years, the youngest six months, the average four years and four months. The onset, in cases in which reliable data could be obtained, was generally insidious, and Koplik is inclined to question the majority of the reports of sudden onset in this disease. Rigidity was absent in fourteen (twenty-seven per cent.); hyperesthesia was lacking in the great majority (ninety per cent.), the patient generally lying dull and giving little attention to surroundings and reacting slowly to irritation. The Kernig symptom was present only in twenty-two cases, and he considers it of comparatively slight diagnostic value. The Babinski reflex, on the other hand, is, he thinks, a more valuable evidence of the tuberculous nature of the disease, as it is exceptional in the cerebrospinal type. Skin eruptions, the *tache cerebrale*, the character of the pulse, and of the respiration have not much value for the diagnosis; vomiting occurs when the ventricles are distended, but is not a leading feature or persistent. Temperature is important; the absence of fever, or persistently low temperature with the cerebral symptoms is strong evidence of tuberculous meningitis. Very high temperature means either a complication or approaching death. Localized pareses only appear toward the close of the disease and then their evanescent character is characteristic. While leucopenia is a presumptive evidence of a tuberculous process the leucocyte count furnishes nothing pathognomonic in this form of meningitis. The eyes of all the patients were examined by experts and some change, varying from optic neuritis to chorioidal tubercle was found present from the beginning in sixty-six per cent. This symptom sharply distinguishes this form from other types of meningitis, especially the cerebrospinal, in which fundamental changes are rare. Skull percussion is of the greatest value

in the early stages of the disorder when the symptoms are still rather equivocal. McEwen's method should be followed; the patient is in an upright position, the head slightly inclined and percussed over the pterion. Koplik found this of value in thirty-four of his fifty-two cases. Lumbar puncture, while admittedly the most valuable precise diagnostic method, is advised only as a confirmatory method after the clinical examination has rendered the presence of tuberculous meningitis highly probable. In other words, Koplik would use it only as a means of confirming or excluding the presence of a disease whose prognosis is hopeless. He believes that careful search will reveal tubercle bacilli by this method in a majority of cases. Although a lymphocytosis of the puncture fluid is not pathognomonic a predominance of lymphocytes is of considerable significance and certainly excludes the diagnosis of certain acute purulent forms of meningitis. Summing up the diagnostic points the author says that the diagnosis of tuberculous meningitis in its earlier stages is possible to-day, whereas it was well-nigh impossible formerly. The slow onset interrupted by periods of irritability, etc., the irregularity of the pulse and respiration, the low or normal temperature, the absence of hyperesthesia, the lack of appetite, and the discovery of hydrocephalus by percussion of the skull will all tend to establish the diagnosis. If after this we can obtain a lumbar puncture, the examination of the fluid in the great majority of cases will put the diagnosis beyond a doubt. The examination of the fundus of the eye is also conclusive in many cases.

Intermittent Tick Fever.—C. F. Kieffer describes what seems to be a new type of fever due to tick bite, observed by him at Fort D. A. Russell, Wyo. The infected region from which all cases originated, partly on the maneuver reservation of the post, is at the head waters of three small streams which together make up Crow Creek. All the patients had been bitten by ticks, specimens of which, sent on to Washington, were identified by Dr. C. W. Stiles as *Dermacentor occidentalis*, the same species which is credited with the causation of Rocky Mountain spotted fever. Kieffer thinks the connection between the tick bite and the fever beyond question. The cases generally correspond to one type. After a short period of incubation (from three to seven days), with brief and ill-defined prodromal symptoms, the attack is ushered in by a chill, with nausea and vomiting and intense and increasing pain in the muscles and joints. The chill lasts two or three hours, and with it a febrile movement begins, the temperature rising to 103° or 109° F., and remaining there as a rule for forty-eight hours, though exceptionally it may last only twenty-four hours. Then a remission occurs lasting about forty-eight hours, the temperature falling nearly to the normal. The disease consists usually of from three to seven such cycles, after which, barring a pronounced anemia, the patient is well. There is another type in which the fever rises ladderlike for two or three days, and there are more marked prodromes and more marked abdominal symptoms (tenderness and splenic enlargement), and the suggestion of typhoid is strong. Blood examination in all cases showed a marked decrease of the red cells and hemoglobin, and the differential leucocyte count gave only a very slight leucocytosis, but a moderate (absolute as well as relative) increase in the number of large mononuclears. Careful search revealed no malarial parasites and nothing like *Piroplasma hominis*. The Widal reaction was always lacking. Quinine, given in all the earlier cases, appeared only to aggravate the discomfort. Kieffer is convinced, however, that arsenic, especially subcutaneously, has a controlling and curative effect on the disease. The best formula is Kobner's; the solution should be sterilized and is used in a dose of from one to two c.c. twice daily. After the acute stage the blood deterioration is to be met by smaller doses of arsenic or the use of the ordinary iron preparation. Five cases are reported.

Is Scarlet Fever a Streptococcus Disease?—From a study of the facts of scarlet fever, L. Hektoen thinks that we are justified in concluding: (1) That the predominant feature of the bacteriology of the throat in scarlet fever is the constant presence of large numbers of *Streptococcus pyogenes;* (2) that the overwhelming majority of the so-called complications and of the deaths in scarlet fever are due to an invasion of the tissues and the blood by this germ; and (3) that in scarlet fever, even when mild, the organism gives evidence of systemic reaction to streptococci by variations in the streptococco-opsonic index and probably also by the formation of streptococco-agglutinins. In spite of all this and of the fact that many of the essential symptoms of scarlet fever can be explained by what we know of the pathogenic powers of the streptococcus, there are serious difficulties in accepting the streptococcal theory of the disorder. There is no analogy in known streptococcus infections with the lasting immunity conferred by even mild cases of scarlatina; there is the reported lack of evidence of streptococcic invasion in certain fulminating cases of scarlet fever; streptococci are scarce in the skin in this disease, notwithstanding the generally accepted infectiousness of the skin lesions; the longevity of the scarlatinal virus, of which there are many reported instances, is contrary to anything known of the streptococcus. The view, therefore, that the germ of scarlatina is yet unknown and that the streptococcus is a concomitant or secondary invader, seems to Hektoen to harmonize better with the facts. We may infer that the throat conditions in scarlet fever are particularly favorable to the *Streptococcus pyogenes,* and the chief significance of the pure scarlatinal virus would seem to be to open the door, so to speak, to streptococci. The need for potent antistreptococcus remedies is as urgent as if it were a purely streptococcus disease. Especially in view of the fact that streptococci grow in virulence in the susceptible animal organism, it is our duty to guard against the transfer of especial virulent strains from patient to patient by insuring adequate measures of isolation.

Pulsus Paradoxus in Pericarditis with Effusion.—W. J. Calvert has had the opportunity of studying two cadavers of patients dying with pericardial effusion. The cadavers were injected and hardened with formalin and then transversely sectioned in such a way as to preserve the position of the organs at the time of death. The conditions found are described by Calvert, and he deduces from them the following explanation of the occurrence of pulsus paradoxus in pericarditis with effusion. 1. Pericardial effusion produces stenosis of the vena cava. 2. This stenosis is relatively compensated by a rise in venous pressure. 3. This compensation falls when the pericardial pressure is greater than the venous pressure. 4. Owing to respiratory change in venous pressure the degree of broken compensation varies in inspiration and expiration —greatest in inspiration, least in expiration. 5. The variation in compensation carries varying quantities of blood to the right heart (and to general circulation)—least in inspiration, greatest in expiration. 6. The respiratory variation in quantity of blood passing to general circulation is sufficient to explain pulsus paradoxus.

Synthetic Chemicals and the Food and Drugs Act.—L. F. Kebler remarks that an entirely new meaning has been given to the word "synthetic," applying it not to the production of new chemical compounds alone, but also to mixtures, and in some cases for the purpose of deceiving the public, as in the well-known case of certain coal-tar preparations. In the Food and Drugs Act the very comprehensive term, "derivative and preparation of same," is purposely employed to cover such cases, and Kebler discusses certain of the synthetic chemicals as they are affected by this law and the changes that have been made by manufacturers to meet the new conditions. Manufacturers are making frequent requests to be allowed to use other names for some of these drugs than those specifically mentioned in the act, and substitutions of drugs less familiar to the public, such as acetphenetidin in place of acetanilid in headache powders, etc., are common. While there was question about including certain chemicals and products in the list of those to be specified on labels, at the time of the passage of the law, the general consensus of the best authorities seems to be at the present time that the list was hardly large enough and that other drugs should be included. He also remarks on some of the food preservatives, noticing the established harmfulness of the salicylates. While benzoic acid and benzoates are claimed by some to be less harmful, this, he says, is yet to be established. Saccharin is another commonly employed agent which should be specified on labels.

Tincture of Strophanthus.—R. A. Hatcher enumerates the advantages possessed by strophanthus over digitalis and digitoxin, and notices as somewhat remarkable the fact that it has not rivaled digitalis more in the favor of the profession. It is prompter in its action, is said to be less cumulative in its effects, is more soluble in water, is less irritant, and, therefore, can be used hypodermically, while at the same time it is much more active and less expensive than digitoxin. It produces much less vasoconstriction in the splanchnic area than digitoxin, and while this is a disadvantage in shock, it is better for diuresis; according to Gottlieb and Magnus, in contrast to digitoxin it produces no constriction of the coronary vessels, which is also an important point when cardiac hypertrophy is desired. Of late years strophanthus has been used with satisfactory results in Holland, Belgium, and France, showing that a fair degree of uniformity of the drug has been obtained. In order to test the conditions here in this respect, Hatcher procured and tested a number

of samples of tincture of strophanthus from the east side drug stores in New York City, comparing them with other samples carefully prepared by himself from the best obtainable seed, as well as with specimens prepared from seed which had been on hand for different periods of time. The physiological test advocated by Fraenkel of determining the amount required to produce systolic standstill of the ventricle per 100 grams of frog in one hour was employed, which has been satisfactorily demonstrated to be an index of therapeutic activity. Cats and dogs were also used in the tests as well as frogs. The experiments are detailed and their results prove, he thinks, that we have a much more uniform product in the tincture of strophanthus, even when obtained from the poorer class of drug stores of New York, than is the case with the digitalis preparation. It may be stated, positively, he says, that there is no difficulty in obtaining tincture of strophanthus in the open market of quite as nearly uniform potency as obtains in the case of tinctures of other drugs which are not standardized, and that the seeds do not undergo deterioration on being kept for several years, possessing in this respect a great advantage over digitalis leaves, which deteriorate rapidly despite care on the part of the pharmacist.

The Lancet, March 23, 1907.

Tests for Acetone in the Urine.—B. J. Jackson Taylor says with reference to the sodium-nitroprusside test, which consists in the darkening which takes place on the addition of acetic acid to a solution of sodium-nitroprusside, urine, and liquor potassæ, that the test is rendered more simple, delicate, and accurate by a slight modification—namely, the substitution of strong ammonia for the liquor potassæ and the elimination of the use of acetic acid. In the ordinary test when the solution of potash is employed there is a uniform reddening of the whole solution which on the addition of acetic acid in the presence of acetone becomes darker when the acid comes in contact with the urine, the darkening passing down as the acid sinks. Therefore, with this test the addition of liquor potassæ to the urine and sodium-nitroprusside yields a red coloration whether acetone is present or not, and it is only after the final addition of acetic acid that the presence of acetone is recognized and then only when there is a fair amount of the latter present. The detection of the presence of acetone is therefore dependent on the darkening of an already darkish red fluid by the final reagent, acetic acid, and the degree of darkening, when acetone is present only in small quantities, is not altogether easy to determine. If, however, strong ammonia replaces the potash solution the test for acetone is as follows: On adding the ammonia to a solution of sodium-nitroprusside and urine the ammonia solution remains on the top; thus there is a clear solution uppermost with the urine solution below. Should acetone be present, even in minute quantity, a well-marked and absolutely characteristic ring of magenta (or petunia) appears within from one to three minutes at the junction of the two fluids and gradually *spreads upwards* pervading the whole of the ammonia solution if acetone is present in considerable amount. In the absence of acetone usually no coloration occurs, but sometimes an orange-red ring forms at the junction of the urine and ammonia solution, but this bears no resemblance to the "acetone ring" described above, hence the presence or absence of the latter is easily ascertained by the method which the author believes has not been generally recognized. The strength of the solution of sodium-nitroprusside is not important, but it is important that it should be prepared fresh and a few crystals dissolved in a test-tube of water are sufficient.

Carcinoma Mammæ in the Mouse.—E. F. Bashford and J. A. Murray describe certain anatomical and pathological features of sporadic tumors occurring in the mouse. Several illustrations are included setting forth their findings in their series of animal experimentations. They believe that these growths are epithelial in nature, are malignant, and are identical with similar malignant new growths in the human subject. This being the case, they claim that their methods have an important practical bearing on the present work of cancer research. They describe the arrangement of the mammary structures in the mouse and present a section illustrating the histology of the normal structures. The tumors first appear as roughly spherical swellings, usually placed asymmetrically with reference to the nipple as in the human subject. The looseness and elasticity of the skin may permit growth to proceed without invasion of the chest wall, although the lungs may be almost completely replaced by metastatic growths. Lymphatic glands in the neighborhood may also show secondary deposits. These mammary growths frequently appear on the removal of the skin to be completely encapsulated by a fibrous layer of varying thickness, but this capsule is usually invaded by strands and columns of tumor cells. The illustrations demonstrate, the authors claim, that they are dealing with new growths of the mammary region of the mouse, which grow progressively (recur after incomplete removal), infiltrate the surrounding normal tissues, and produce metastases of the same histological type in the lungs and lymphatic glands. They lead to the death of the animal. The conclusion is inevitable that they are malignant new growths of the mamma.

Opsonins and Immunity.—J. L. Bunch says that the opsonic index of a patient to a given microorganism is simply the expression of the relative power of the patient's opsonins to influence the taking up of the germ by phagocytes as compared with that of a healthy individual. In other words, the opsonic index is a definite expression of the patient's relative immunity. An increase of the opsonic content of the blood in disease is brought about by the injection of the appropriate vaccine. If the right dose is given a short "negative phase" will be followed by a well marked positive phase, during which the antibacterial power of the blood is increased and the resistance of the patient to the disease is increased. After tubercle inoculations this improved power of resistance may be maintained for several weeks, but, as a rule, it falls back again after ten days or a fortnight, and a further dose of the vaccine is necessary. Only the minimal dose must be employed which will produce a satisfactory response and this must not be increased until it ceases to produce its effect. The dose, moreover, must not be repeated until the effect of the preceding dose is passing off. If it were possible to produce a summation of positive phases it would be advantageous to give successive doses at short intervals, so as to produce a maximal favorable effect, but such summation is not possible in the case of tubercle. Each inoculation, therefore, produces its effect independently and it remains to take the greatest advantage possible of the increased elaboration of protective substances which the artificial stimulus has produced.

French and Italian Journals.

Protective Function of the Liver Against Intestinal Toxins.—G. A. Petrone and Aurelio Pagano describes the functions of the liver as protective against the vegetable alkaloids, many mineral poisons, foreign substances that occasionally find their way into the intestine, such as ammonia and the aromatic substance due to putrefaction of albuminoids, peptones, albumins, soaps, and alcohol. Also against saturated solutions of bicarbonate of soda, sulphate of soda, chloride of soda, adrenalin, sulphuric ether, chromic acid, and phosphorus. It protects against some microorganisms, and does not against others. It acts against tetanus toxin, cholera, bacillus, coli, alcoholic extracts, putrid materials, and alcohol typhoid materials. The action against bacteria is due to phagocytosis exerted by the epithelium of the blood-vessels, according to some. Others refer it to the amount of glycogen contained in the liver. The authors have made experiments to ascertain whether there is a protective action against the ordinary intestinal toxins. The toxic substances were injected into a mesenteric vein and into a peripheral vein and the results compared. The results lead them to conclude that the liver exerts a marked protective action against ordinary intestinal toxins. The first barrier against these toxins is furnished by the walls of the gastrointestinal tube, and many of them are thus removed. Those that are left meet a second obstacle in the hepatic gland, with its rich circulation and innumerable endothelial elements. The lung then acts on those that have escaped the liver, and last of all the blood by means of circulating leucocytes continues the action.—*La Presse Médicale*, February 13, 1907.

Chromatophore Cells and Langerhans Cells in the Skin.—E. Bizzozero has made examinations of many condylomatous growths of the skin, of elephantiasis, and matophore cells and Langerhans cells in the skin. He presents these conclusions: That the interepithelial chromolluscum fibrosum to determine the presence of chromatophore cells are connective tissue cells containing pigment, which have immigrated from the cutis. That the structure of the nuclei varies according to the conditions of nutrition in which they existed. That the nucleus in inflammatory processes may multiply by direct division without any division of the protoplasm, or by indirect division followed by division of the protoplasm. That the chromatophore cells progressing toward the surface of the skin may be broken up into minute detritus and the pigment spread in the interepithelial spaces, or may be gradually destroyed later. That in the group of Langerhans cells must be included pigmented chromatophores, unpigmented chromatophores, and those whose granules are only brought out by nitrate of silver; excluded should be epithelial cells, migrating cells, and nerve cells.—*Archivio per le Scienze Mediche*, Vol. XXX, Part 6.

Book Reviews.

Nouveau Traité de Médecine et de Thérapeutique. Publié en Fascicules sous la direction de MM. P. Brouardel et A. Gilbert, Professeurs à la Faculté de Médecine de Paris. XI. Intoxications. Par P. Carnot, E. Lancereaux, M. Letulle et R. Wurtz, Professeurs Agrégés à la Faculté de Médecine, Médecins des Hôpitaux, Paris: J. B. Baillière et Fils, 1906.

The System of Medicine of Brouardel and Gilbert has, in the new edition, been made much more accessible by its publication in small sections, each complete in itself and separately purchasable. The volume on "Intoxications" is in every way an admirable contribution to the literature of the subject. Paul Carnot, in a brief review of the chemical and physiological mechanism underlying poisonings in general, has written an excellent introductory chapter. While there is a certain uniform thoroughness in the treatment of all the following sections, by far the most satisfactory are the one on "Lead Intoxications," by Letulle, and the truly masterful treatise on "Alcoholism," by Lancereaux. There have probably been no more excellent studies made of this important subject than this one of Lancereaux, who, without neglect of the purely medical aspects of the matter in hand, deals at length with the statistical and sociological problems involved, the subdivision on "Hereditary Alcoholism" and the one on "Legislative Prophylaxis" being particularly good. The authors have made a very thorough use of the literature of all countries, and the book gives the impression of bringing its subject completely up to date. Throughout there is a literary quality and skill of treatment which make its pages easy and pleasant reading, a feature which may well be recommended to many of our American writers of text-books.

Who's Who, 1907. An Annual Biographical Dictionary. Fifty-ninth Year of Issue. London, Adam and Charles Black; New York: The Macmillan Company, 1907.

This is the original of all the Who's Whos, national, municipal, professional. It is not strictly national in its scope, but includes biographies of some of the most prominent men in science, letters, arts, finance, and politics in the countries of Europe and America. Chiefly, however, it gives information concerning residents in the United Kingdom and its colonies. The book will be found very serviceable to all readers of newspapers and reviews who want to know something about the men of Great Britain and Ireland who are, without the information here given, only names to most of us. The data about Americans mentioned in the work appear to be in the main correct, though we notice that the name of the late Albert Bierstadt, the artist, is retained in the book as though he were still living.

The Toxins and Venoms and their Antibodies. By Em. Pozzi-Escot. Authorized translation by Alfred I. Cohn, Phar. D. First Edition. New York: John Wiley & Sons, 1906.

The first part of this book deals with generalities regarding toxins and antitoxins; the second half treats of the toxins proper—vegetable and animal toxins, microbial toxins, and the venoms. The book is small, and only the merest outline is given; but it will serve as a useful introduction to the more detailed study of an important subject. The value of the book is increased by numerous footnotes, which refer to fuller sources of information.

The Practice of Obstetrics. Designed for the use of Students and Practitioners of Medicine. By J. Clifton Edgar, Professor of Obstetrics and Clinical Midwifery in the Cornell University Medical College; Visiting Obstetrician to the Emergency Hospital of Bellevue Hospital, New York City; Surgeon to the Manhattan Maternity and Dispensary; Consulting Obstetrician to the New York Maternity Hospital. Third Edition, Revised. With 1,270 illustrations, including five colored plates and 38 figures printed in colors. Philadelphia: P. Blakiston's Son & Co., 1907.

It would seem that there is no need to do more than announce the appearance of a new edition of this standard work. Still, admirable as were the two former editions, the present volume contains new matter that adds to its value. There are new sections on appendicitis complicating pregnancy, tapeworm complicating pregnancy, hematoma of the vulva, fibroma molluscum gravidarum, lactation atrophy of the uterus and breasts, brachial birth paralysis, vaginal incision and drainage, new history charts for institution work. In addition the following subjects have been more or less rewritten: The development of the ovum, embryo, fetus, fetal membranes, and fetal structures; chorioepithelioma malignum; the treatment of placenta prævia; the toxemia of pregnancy; the etiology of eclampsia; ectopic gestation; the treatment of pelvic deformity; morbidity in the puerperium; indications for the induction of abortion and premature labor; the forceps; cesarean section; vaginal cesarean section; Porro-cesarean section; complete and incomplete abdominal hysterectomy. Although much new matter and 140 new illustrations have been added, the size of the present volume has been reduced by about one hundred pages; this has been accomplished by rewriting, condensation, the omission of obsolete matter, and a reduction in the size of some of the illustrations.

Self-Propelled Vehicles. A Practical Treatise on the Theory, Construction, Operation, Care, and Management of All Forms of Automobiles. By James E. Homans, A.M. Sixth Edition, Revised and Enlarged. With Upwards of 500 Illustrations and Diagrams, Giving the Essential Details of Construction and Many Important Points on the Successful Operation of the Various Types of Motor Carriages Driven by Steam, Gasoline, and Electricity. New York: Theo. Audel & Co., 1907.

Thanks to the skill of designers and makers, the construction of motor vehicles is each year becoming simpler and at the same time more effective. Even the least complex, however, demands of its driver a considerable degree of technical knowledge if it is to be operated profitably, and the present is an admirable text-book for tyros, and work of reference for the more experienced. In accordance with its practical importance the greatest amount of space is given to the gasoline vehicle, though the application of steam and electricity as motive powers is adequately described. The more important structural features of most of the well-known foreign and domestic cars are discussed and illustrated, and much practical information is given, both in regard to routine driving and also concerning the unexpected happenings for which automobiles are so notorious. The book is well indexed and is paragraphed with side heads in such a way as to make it convenient for reference, and it may warmly be commended as a complete, easily comprehensible handbook on the anatomy, physiology, pathology, and therapeutics of motor vehicles.

Manuel d'Histologie Pathologique. Par V. Cornil, Professeur à la Faculté de Médecine, et L. Ranvier, Professeur au Collège de France. Avec la Collaboration de A. Brault, Médecin de l'Hôpital Lariboisière, et M. Letulle, Professeur Agrégé à la Faculté de Médecine. Troisième Édition. Tome Troisième. Avec 388 gravures en noir et en couleurs dans le texte. Paris: Felix Alcan, Éditeur, 1907.

The first volume of this very elaborate system was devoted to the principles of pathology, to tumors, and to the pathology of the bones, joints, and serous membranes. The second volume contained the discussions of the pathology of the muscles, blood, and marrow, and in the present work the central nervous system, the cardiovascular system, the lymphatic system, the spleen, and the larynx are considered. The volume is a very large one of 1,170 pages, with 388 illustrations, many of them in colors, and nearly all of unusual interest and excellence. The first 850 pages comprise a series of exhaustive articles on the pathology of the brain, cord, and peripheral nerves by Gombault, Riche, Nageotte, and Durante. The vascular system is treated of by Marie in 150 pages; Bezançon covers the lymphatic system in 100 pages more, and the volume is closed by an article on the larynx by Legry. This last does not seem properly to belong with the other subjects included in this section, since it forms the beginning of the work on the respiratory system which is to follow in the fourth and last volume of the system shortly to be published. The eminence of the two editors-in-chief sufficiently guarantees the quality of the text, and the work is an important addition to the literature of pathological histology.

Mercer's Company Lectures on Recent Advances in the Physiology of Digestion. Delivered in the Michælmas Term, 1905, in the Physiological Department of University College, London. By Ernest H. Starling, M.D., F.R.S., Jodrell Professor of Physiology. With twelve illustrations. Chicago: W. T. Keener & Co., 1906.

One of the most important of the recent advances in our knowledge of the physiology of digestion concerns the nature of the stimuli which evoke the gastric and pancreatic secretions when food or chyme enters the stomach or duodenum. Formerly supposed to be due to reflex nervous activity it now appears that the secretory stimulus is largely a chemical one depending on the formation of a hormone at the seat of stimulation which then reaches the gland in question through the blood stream. The steps which have led up to the discovery of these gastric and duodenal secretins are traced in detail in these lectures, as well as many other phases of digestion which have been made the subjects of recent investigation.

Society Reports.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

208th Regular Meeting, Held March 1, 1907.

THE PRESIDENT, DR. ROBERT ABBE, IN THE CHAIR.

A Case of Cervical Rib, with Symptoms.—Dr. LEWIS A. CONNER presented a girl, seventeen years old, with bilateral cervical ribs, who had been shown to the society one year ago. At that time she complained of occasional slight pains in her left shoulder, but it was impossible to tell whether or not the pains were related to her supernumerary rib. Since that time the pain had become more constant and severe, and now was present most of the time. It no longer was felt only in the shoulder, but frequently radiated to the elbow. There was no evidence of muscular atrophy on the affected side, and the left deltoid showed only slight diminution in faradic irritability. Power in the two arms was equal, but the left tired more easily. The skin sensibility was not disturbed. In the light of the developments of the past year there was now little doubt that the symptoms were the result of pressure of the cervical rib upon the nerve trunks, and if these symptoms increased, the question of operation would have to be considered. In reply to a question, Dr. Conner said this condition of cervical rib was frequently bilateral, but not always. The operation for the removal of the rib was regarded by surgeons as sometimes quite a difficult one. The symptoms associated with the condition were apt to develop during early adult life, which was perhaps due to the elongation or increasing rigidity of the ribs at that time.

Local Thermotherapy.—By Dr. W. GILMAN THOMPSON. (See page 592.)

Dr. BEVERLEY ROBINSON said that in spite of the undoubted accuracy and scientific value of the investigations of Dr. Thompson along the lines indicated in his paper, his findings were not in entire accord with clinical experience in the use of local thermotherapy, and until the art of medicine could be reduced to an exact science, such discrepancies would doubtless continue to exist. For example, the use of ergot to control pulmonary bleeding was generally regarded as utterly unscientific; still, Dr. Robinson, said, he invariably gave the drug in such cases, and had a certain amount of faith in its efficacy.

Dr. ANDREW H. SMITH said that very early in his medical career he had been instructed to the effect that when heat or cold was indicated as a local application, either one could be selected, the choice depending on the personal comfort of the patient and the therapeutic effect apparently varying with the subjective sensations. That general rule was still more or less observed by practitioners. When theory failed we resorted to practical results. When, in a certain case, we found that cold aggravated the pain, while warmth apparently allayed it, we were justified in resorting to the later, or *vice versa*. The practical utility of thermotherapy could not be doubted, whatever the scientific basis for it might be. For instance, a toothache was always aggravated by cold applications, and usually eased by hot ones. The same was true in the pain accompanying inflammations of the middle ear.

Dr. JOHN WINTERS BRANNAN inquired whether in Dr. Thompson's opinion the abdominal ice coil was of use in typhoid fever, apart from cases in which there was intestinal hemorrhage. The speaker said that last autumn, when he was endeavoring to induce the physicians of Harlem Hospital to place their typhoid patients on the balconies to get the benefit of the fresh air, they objected on the ground that it interfered with the use of the ice coil. In cases of sprained ankle, Dr. Brannan said, he had seen the swelling and pain rapidly disappear under the use of hot applications.

Dr. GEORGE L. PEABODY recalled Dr. Thompson's previous work in connection with this subject, and stated that he had long been in entire accord with the views expressed, which contained nothing antagonistic to the use of local thermotherapy in the treatment of certain conditions. Personally, Dr. Peabody said, he confessed great faith in hot applications for pleuritic pains. In certain other similar conditions cold seemed more efficacious than heat, and both seemed to accomplish the same result in different ways. While local thermotherapy did not affect the internal temperature directly, still in a reflex manner it influenced the blood supply of the part, reducing it either by constriction of the afferent vessels, thus preventing the inflow of blood, or increasing the outflow of blood by its effect on the efferent vessels. In both cases there would be a diminution of the amount of blood at the site of the inflamed part. The speaker said he had an abiding faith in the relief of appendicular pain by the continuous application of an ice bag, and under its use he had seen many cases in which the acute symptoms subsided, permitting a subsequent interval operation.

Dr. FRANCIS P. KINNICUTT said that while he was unable to offer any scientific explanation of how heat and cold acted, respectively, in relieving pain, their efficacy in that regard had been borne out by clinical experience. The pain of appendicitis for example was often materially diminished by cold applications. The same was true of the pain of pericarditis and even of deeply seated organs. The explanation by Dr. Peabody of the similar results effected either by cold or heat was of much interest. While the laboratory tests bearing on this subject made by Dr. Thompson were very thorough and interesting, Dr. Kinnicutt said he did not think they were entirely conclusive. For example, in trying to ascertain the effect of local thermotherapy upon the blood supply of a part, mere visual inspection would be insufficient, as the human eye would be incapable of recognizing slight changes either in the caliber of the vessels or in the rapidity of the blood current. Slight blanching or reddening of the parts were difficult to recognize, yet slight changes in the local circulation might suffice to relieve the pressure on the nerve filament, to which the pain in many cases should be ascribed.

Dr. CHARLES L. DANA thought Dr. Thompson had certainly established the fact that our therapeutic results from local heat and cold were not due to any direct transmission of the heat or cold to the internal organs. The inference to be drawn from his investigations was that there was a very intimate relationship between the cutaneous nerves and the vascular condition of the internal organs. Dr. Head had shown that variations due to acute pathological processes in the deep viscera were reflected very quickly upon the cutaneous organs. In chronic conditions this relationship was less intimate, as a certain degree of equilibrium was established. It could be legitimately inferred, however, that external applications likewise produced definite reflex effects on internal organs, and the subject of local thermotherapy therefore resolved itself into a study of how much we could effect by such reflex action. The speaker recalled the time when Chapman's ice bags were very much in vogue as a therapeutic measure, and he had resorted to the use of long ice bags and short ice bags on the spine in the treatment of locomotor ataxia and spinal irritation and various other nervous affections. In chronic conditions he had never seen any results from the use of such applications, but in acute conditions, such as headache and some forms of spinal pain and paresthesia, he had seen relief follow the use of such applications. After cerebral apoplexy it was the usual thing to apply an ice bag to the head, and while this rendered some of these patients more comfortable by relieving the headache and the constricting sensations, it had no direct effect on hemorrhage. In local pains, such as the various types of neuritis, the application of heat or cold was often very grateful, and in such cases the benefit was due, per-

haps, partly to direct transmission and partly to reflex action. Dr. Dana said he was in hearty accord with the reader of the paper that intelligent local thermotherapy should be more generally adopted and carried out in our general hospitals.

The President, Dr. Abbe, said that from a surgical standpoint he thought there was no doubt that local applications of heat and cold had a controlling influence on deep inflammatory processes. For instance, in synovitis of the knee-joint, the application of an ice bag was of undoubted value, reducing the inflammatory process and diminishing the size of the distended joint. In appendicitis the application of cold was frequently followed by a rapid reduction of the engorgement of the deep-parts which were the seat of inflammation, sometimes to such an extent that the strictured condition of the appendix, swollen to the point of obstruction, yielded and the attack would be over for the time being. In looking for a possible explanation of the beneficial effects of local thermotherapy, Dr. Abbe said he would be inclined to ascribe them to vasomotor influences. This was evidenced in the, at times, almost magical effects of hot applications to the forehead or nape of the neck in migraine, resulting, apparently, in relieving the local congestion of the vessels.

Dr. Robinson said that in certain cases where heat was indicated, he had found the electric pad more serviceable than the hot water bag. He also referred to the value of the actual cautery in old heart cases with dilatation and pain.

Dr. Thompson, in closing, said that in his paper he had admitted the value of local thermotherapy in various conditions of pain, but his chief contention was that it was difficult, if not impossible, to reach deep-seated hemorrhage, congestion, or inflammation by the ordinary methods of applying heat or cold, and that whatever effect such applications had in those cases, they were certainly not due to direct thermic transmission. This, of course, did not apply to cases of toothache, alveolar abscess, etc., where the heat or cold came in close contact with the source of irritation. The electric pad, to which Dr. Robinson had referred, was superior to the hot water bottle only because in the former the source of the heat was constant. The heat of the thermocautery was only momentary, and its beneficial effects were the result of its stimulating rather than its heating properties.

He said the changes in the circulation referred to by Dr. Kinnicutt were probably brought about by reflex action, perhaps distantly transmitted. For example, any stimulus applied over the precordium, in order to affect the deeper parts, might travel through the spinal centers and from thence be transmitted to the pleura and pericardium, and perhaps to the heart itself. The speaker said he was inclined to doubt that heat iself had any deep penetrating influence. Our knowledge of cutaneous stimulation and its effect on the internal circulation was slight. It was a far cry from the cutaneous circulation to the renal circulation, and a long distance for the nerve currents to travel. It was curious that there was such a close relationship, apparently, between certain cutaneous areas and some organ immediately underneath with which they had no direct physiological or nervous connection, although the clinical relationship was undoubted.

In speaking of the use of the abdominal ice coil in typhoid fever, Dr. Thompson said he had formerly employed it in patients who were too ill to be given tub baths, or where a hemorrhage had occurred and it was undesirable to disturb the patients. He had become convinced, however, that the ice coil was of little practical utility in these cases.

Dr. Dana said that the connection between the reflex effects of local stimuli and deep-seated pains, like those of pericarditis, was perhaps not as complicated as Dr. Thompson had suggested. On the contrary, a very close relationship had been shown to exist between the heart and pericardium and segmental areas of the overlying skin, and applications of heat or cold to the latter would influence corresponding sympathetic nerves. Dr. Dana said that at times the simple application of methyl chloride to the skin relieved pain which appeared to lay in one of the internal viscera. The only explanation he had to offer for this phenomenon was that this stimulation of the cutaneous nerves gave rise to inhibitory influences, thus producing interfering currents.

Dr. Conner said that if deep visceral pain produced definite and constant areas of skin hyperesthesia, as Head had so clearly demonstrated, the deduction seemed perfectly reasonable that grateful applications of those cutaneous areas might tend to relieve pain located in deep-seated organs.

Dr. Peabody referred to the value of the alcohol poultice, even in cases where the pain was deep-seated, as in acute peritonitis. In making these applications it was essential to have the epidermis absolutely saturated with alcohol, which could be applied upon several thicknesses of cheese-cloth, properly covered. The method was not advisable in areas where the epidermis was very thin, as in the scrotal region. He had often found it very efficacious in relieving the pain of phlebitis. The alcohol apparently paralyzed the blood-vessels, increasing their lumen and producing a blanching of the parts. In regard to the electric pad, to which Dr. Robinson had referred, Dr. Peabody said he had recently had two of these pads take fire while in use, and in one instance the patient's bed was set on fire. The conflagration was explained by the manufacturer on the ground of improper voltage.

Dr. Robinson said that in some cases of deep-seated pain he still had faith in the old-fashioned method of drawing blood by the use of leeches, which he regarded superior to wet cupping.

Dr. Andrew H. Smith suggested that the lymphatics possibly played an important rôle in the more chronic forms of pain that were relieved by the application of heat or cold.

Dr. Thompson said he also had seen a conflagration of one of the electric pads. This possible danger attending the use of the pads should not be lost sight of.

Aneurysm of the Arch of Aorta, which Ruptured into Esophagus in a Young Woman without External Evidence of Syphilis.—Reported by Dr. George L. Peabody, with specimen. (See page 595.)

Dr. Andrew H. Smith said that in a case of aortic aneurysm observed at the Presbyterian Hospital about fifteen years ago it was possible to detect a distinct souffle by placing the bell of an ordinary stethoscope in the patient's mouth, with the lips firmly closed around the tube. In that case the souffle could not be heard by the ordinary method of auscultation.

Dr. Abbe recalled one case of aortic aneurysm where the tumor imparted a marked impulse to the stomach tube.

Tuberculosis of the Iris Cured by Tuberculin Injections.—Dr. Charles Stedman Bull reported this case.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held February 28, 1907.

Dr. Howard C. Taylor in the Chair.

Degenerating Fibroid Complicating Pregnancy; Myomectomy, with Resection of Adherent Omentum; Continuation of Pregnancy.—Dr. F. A. Dorman presented a degenerating fibroid which he had removed from a patient thirty years old. She had been married thirteen months. Her childhood was healthy, her menses were regular, flowing five days, normal in amount, and without pain. Within the past year a miscarriage occurred at the third month; this was brought about possibly by over-exertion. At the

time of operation she was nearly five months pregnant. In the early months of pregnancy there had been fairly constant paint over the lower mid-abdomen, worse upon exertion, but this had gradually lessened for the past two months. A week before operation she began to have cramping pains over the lower abdomen, so severe that she was obliged to stay in bed part of the time. She had some nausea and vomiting. There was no constipation, no chills, or fever. On admission to the hospital two days before operation, the pain had lessened, the temperature was 99.8° F. and the pulse 98. The next day the pain was more severe and operation was decided upon. The abdominal examination showed a five months pregnant uterus, with a protruding mass, fairly firm, about the size of a small orange, extending forwards and near the apex of the fundus to the left. A median abdominal incision was made exposing the uterus, and the tumor was exposed in the wound. It was found to be a fibroid attached to the left side of the uterus near the anterior surface of the left horn by a broad base. It was also attached quite firmly to the omentum and to several loops of small intestine. The adhesions were separated and the fibroid removed by a circular incision about its base, and shelled out by careful enucleation. The depth of the uterine wound was nearly that of the thickness of the uterine muscle. The bleeding was profuse, but controlled by pad pressure, and the wound was sewed up by layer catgut sutures. The matted section of the omentum was removed by chain ligature. The patient was kept quiet for two days by morphine and until the fifth day by codeine. The convalescence, except for a temperature of 102.6° on the fourth day, was normal. She was discharged on the seventeenth day. Labor came on, following a rupture of the membranes, just before the eighth month. The pains were very insufficient and the cervix rigid. After nearly forty-eight hours' labor, with the cervix two-thirds dilated, he placed her under chloroform, completed the dilatation digitally, and delivered her of a four-pound baby by medium forceps. Both mother and child did well.

Dr. Brooks H. Wells said this report was interesting on account of the condition being a rare one; ordinarily fibroids in the fundus of the uterus in the pregnant woman did not require any interference. It was unusual to find, too, a fibroid undergoing degeneration in a uterus so well nourished. As to the way these women stood operation, his experience was that they continued in the pregnant state provided the operation was done cleanly, and if the uterine cavity was not punctured. His experience was limited to four cases. In one the woman was about five months pregnant, and she had a dermoid cyst of each ovary. The ovaries and tubes were taken out close to the uterus. She was seen with Dr. Mundé and it was believed that she would abort. The baby was delivered at full term. He then saw another case with Dr. Mundé where there was a large ovarian cyst; this was removed and the woman went on to full term. He had had two other cases in his own experience; in both there was a large cyst, which was removed during pregnancy, and the patients went on to full term without difficulty.

Dr. S. M. Brickner said that in two years they had had four cases at the Mount Sinai Hospital where operations were undertaken during pregnancy and none had aborted or miscarried. With regard to the point raised as to the rarity of necrosis, which was the most common form of degeneration, where the fibroid was pedunculated or twisted, or where there was a submucous fibroid, the fibroid was most likely to become necrosed. He recalled one case where the woman aborted at six and a half months; she ran a temperature of 101° before and after the abortion for some days, with tenderness and pain in the right iliac region. An examination failed to disclose any exudate or involvement of the appendages. He decided then to examine her under an anesthetic and he was surprised to find a good sized submucous fibroid, which was easily enucleated. She made a good recovery. He had seen within the last year a rather large subperitoneal fibroid which occupied the fundus uteri, which became necrotic and which was removed at the fourth month of pregnancy. The symptoms were similar to those presented in Dr. Dorman's case.

Dr. George H. Balleray said that he never operated for fibroids in pregnant women. He had seen several cases, but none had degenerated. After delivery they disappeared within eighteen months or two years. He said he had operated during pregnancy for the removal of ovarian tumors in six cases, and all went on without aborting. He had also operated for leaking pus tube in the fourth months of pregnancy. The tube was removed and she did not abort, but went on to the sixth month, when premature delivery occurred. He asked Dr. Dorman what the change was that occurred in the fibroid presented by him. He thought it was rather firm and had rather a healthy appearance.

Dr. Dorman, in reply to Dr. Balleray, said he had not had the pathological examination made, but the tumor as shown differed now from what it appeared to be in the fresh state. It was then acutely inflamed at the point of attachment. The incision made was about one-half to three-quarters of an inch in depth in the uterine wall. It was a circular one, converted into a longitudinal one. He had at present a case of double dermoid cyst in a five months pregnant woman; both ovaries were prolapsed and there was the irregular feeling of the dermoid ovarian cyst. There was one twist in one of them.

Fibroid Tumor of Large Size; Operation; Continuation of Pregnancy.—Dr. Edward J. Ill of Newark presented this specimen, which weighed sixteen pounds, and was removed from a woman who was in the fifth month of pregnancy, with no miscarriage following. In twelve years he had had forty-five cases of uterine fibroids complicating pregnancy, and in only one case was it necessary to remove the tumor. He said he had often wondered if the old country doctors had ever seen such cases, where the presence of the tumors was the cause of death. One old doctor he questioned had never seen one case in thirty-five years' practice and he had records of over two thousand cases of labor. He had often wondered what became of these tumors and how they behaved. The specimen he presented was of special interest. The woman was delivered one year ago in a Western State. She was thirty-eight years old and this was her first child. Then followed a long siege of pain and fever, which was attributed to an autointoxication. She got perfectly well and it was thought she was pregnant again. An examination proved that she was not pregnant and she menstruated again. After that the tumor appeared to become soft and, fearful of having trouble during pregnancy, Dr. Ill agreed to remove the tumor for her. The indications were not well drawn, except that the tumor was soft. When he got down to and into the tumor he found a large pocket containing yellowish-gray grumous material, of which he removed at least one pint. He presented the remains of the uterine fibroids. The uterine cavity was small. She had no temperature and no annoying symptoms. The fluid must have been sterile because there was no temperature. This case might have gone on to cure if it had been left alone and if she had not again become pregnant.

Some Causes of Failure in Plastic Operations.—Dr. Samuel M. Brickner read this paper. He asked what constituted a failure in the results of a plastic operation. It might be anatomical, functional, or symptomatic failure. Three important elements entered into the performance of a plastic operation, namely, the patient, the operator, and the technique of the operation, including the after-treatment. The selection of patients for a plastic operation was the first important step. Diabetes, chronic nephritis,

exophthalmic goiter, an active tuberculosis, were contraindications to operation, except in cases of rectal or vesical fistula, or complex lacerations of the perineum, which threaten the patient's life or which made her life a burden. Aged women, who could be made comfortable with the aid of pessaries, were better treated thus than by operative intervention. Unless a perineal laceration could be repaired within a few hours or a few days after the birth of the child, it was far better to wait a full eight months; before this period had elapsed the tissues were not only exceedingly vascular, making hemostasis difficult, but they were more brittle. Women who were "run down" should first be subjected to the proper sort of tonic treatment. Plastic operation upon the vagina should be employed only by those thoroughly familiar with gynecological work. Gynecologists could prepare themselves for this plastic work only by unremitting toil and ceaseless work. The operator should be born with, or must acquire, a "plastic imagination." No factor contributed to failure more frequently than incompleteness. To attempt to correct a complete laceration of the perineum by the flap-splitting method without denuding and repairing the invariable vaginal laceration, involved inevitable failure; and yet this was not an uncommon blunder. Perhaps the most common error in this category was the suture of the vaginal mucosa in either anterior or posterior colporrhaphy without including the fascia in the former case and the muscles and fascia in the latter. An operation for cystocele was not complete unless it included pushing back the bladder and its retention in its new position by some method of suture. The denudation or the suture of the underlying tissues must be so done that the suture of the mucous membrane would lie in the median line. It was also important that like tissues be joined. Many an extensive and well-performed plastic operation had been ruined because the patient's bowels had moved during the procedure. If the finger was to be inserted into the rectum while suturing the posterior vaginal wall, it should be protected by a sterile finger-cot or glove; but the tying of sutures should then be done by an assistant. A too liberal use of antiseptics and a too vigorous scrubbing of the vagina might so injure the mucous membrane that it would not readily heal. A prominent cause of necrosis of tissue following plastic operation lay in tying the sutures too tightly, especially if they were of chromic catgut. Sutures should not be placed too near each other. Personally he did not believe that it made much difference what kind of suture material was used, provided the stitches were placed at proper intervals, were not tied too tightly, and, if of silk or silkworm gut, were removed before they had torn through, or if they strangulate the tissues, or when they became loose. Perfect hemostasis was an important desideratum in plastic operations. A frequent source of functional failure in plastic operations lay in the too tight closure of the vulvar outlet; the reverse was also true. With regard to the after care of plastic cases, there was one blundering error of permitting a full-sized rectal tube to be passed in cases of complete laceration of the perineum. A suitable length of time should pass before the bowels were permitted to be moved. Catheterization must be rigidly aseptic, for a woman was not cured who left their hands with chronic cystitis. This again was a subject for scrupulous teaching to nurses.

Dr. Brooks H. Wells said that he subscribed most heartily to everything the doctor had stated, and emphasized the fact that the patients should be properly prepared before operation. To get the best results, the patient should be in the hands of a well-trained gynecologist. He emphasized the importance of a wide separation of the bladder from the underlying tissues in order to get the most perfect results. He called attention to the persistent and sometimes serious hemorrhage that occurred from the veins at the base of the bladder; this happened when the operator went a little deeper in the tissues than was necessary. He did not like to tie vessels in plastic operations. The smaller the number of ligatures used in plastic operations the better the healing. In operations upon the posterior wall it had always seemed to him that the shape of the denudation was the least important thing; the most important thing was to recognize the nature of the injury in that particular case and to try to overcome it. In nearly all these cases, where the indications were clear for operation upon the posterior wall, one would find marked relaxation of the fibers of the levator ani muscle. In examining such a case one should insert the finger and the muscle bundle would be found quite well up. Unless the sutures were placed so as to bring these fibers together good results would not follow. The fingers should be kept out of the wound and away from the business ends of the instruments. If gauze pads were used, they should be used at once. One should irrigate with normal salt solution. In complete lacerations of the perineum an important point was to make the incision above the angle of the tear between the rectum and the vagina, a little way up in the mucous membrane of the posterior wall, and dissect down, turning down and making this apron cover the rectum. This avoided sutures in the mucosa of the rectum and the infection of the wound. In cases of complete prolapsus the method which gave the greatest success was a high amputation of the cervix, as Kelly did, following it up with an operation upon the anterior and posterior wall; then make an incision in the median line of the abdomen and do a ventral fixation, picking the uterus up from the front and stitching it against the anterior wall.

Dr. George H. Balleray said that it was a great mistake to operate too soon after delivery, when the parts were not in proper condition for healing. That was the fault frequently found in the cases sent to him. Preparatory treatment was certainly indicated. In many of the rebellious cases of prolapse it seemed to him better to remove the uterus per vaginam and then to do an anterior and posterior colporrhaphy if necessary.

Dr. L. J. Ladinski said that plastic work was underrated as a rule, not only by men with proper training and ability and technique, but even by those who were looked upon as gynecologists. Such work was usually handed over to members of the house staff. Personally he felt that his plastic work in the gynecological department had been more satisfactory than in others, and the patients were more grateful. The patients were always grateful. Whereas patients operated upon for tumors, with their lives saved, always had some cause for complaint subsequently, either from loss of function or some little pelvic trouble, going from one physician to another, and they were not at all grateful. Sharp rather than blunt dissection should always be done; it removed less tissue and left a better surface behind.

Dr. Wells said that when he spoke of sharp dissection it was in reference to the perineum.

Dr. S. M. Brickner said in reference to the point raised by Dr. Wells in operations for complete prolapse of the uterus, that no operation would be a successful one unless one precaution was taken, viz., after amputation of the cervix and when the sutures were taken in the continuance of the plastic operation, as each suture was tied the cervix should be pushed back a little. If that was not done when the posterior colporrhaphy was done, the stump of the cervix would become strangulated between the sutures above it in the anterior and posterior wall and slough away.

The Diagnosis of Early Pregnancy.—Dr. L. J. Ladinski read this paper. (See page 597.)

Dr. E. McDonald said that in a discussion on the early signs of pregnancy held in Philadelphia the speakers, among whom were Hirst, Baldy, and others, depended upon one

sign for the diagnosis of early pregnancy, and this Dr. McDonald thought was a mistake. In a study he presented there he gave the findings in 100 cases and he thought that a résumé might be of interest to the members of the Section. This was as follows:

Dr. Sidney D. Jacobson said there was no occurrence in the whole life history of woman which so profoundly affected her body and mind as the advent of pregnancy. Every organ in the body was influenced directly or indirectly by constructive metamorphosis which went on within the uterus. Thus the thyroid gland enlarged, the heart hypertrophied, the kidneys, liver, and digestive tract showed the strain of increased metabolism. The skin became pigmented and both the cerebrospinal and sympathetic nervous systems gave evidence of functional disturbance. The blood also was altered profoundly in its character; it became hydremic, and a leucocytosis was found. This leucocytosis was progressive and reached its highest point just before delivery of the child and then dropped below normal for several days or weeks. Rokitansky pointed out that during pregnancy calcareous plates were deposited upon the inner table of the patient's skull, and he called these puerperal osteophites. Because they were rather elementary Dr. Jacobson said that he would refrain from describing the minute histological changes which took place in the genital tract of the pregnant woman, but would point to some interesting facts which perhaps were not so well known or so constantly taught. (1) The uterine and ovarian arteries enlarged so that at term they were the size of a crow's quill, while the veins became as thick as a man's little finger. (2) The unstriped muscular fibers which composed the bulk of the uterine musculature became elongated to ten times their previous size, viz., 500 microns. (3) According to Levret the surface of the virginal uterus was about 16 square inches; at the end of pregnancy this had enlarged to 339 square inches. (4) According to Krause the capacity of the uterus at term was 519 times as great as that of the virgin uterus. Roughly, this would be like the difference in size of a rowboat and an ocean steamer. (5) The weight of a nonimpregnated normal uterus was about 50 grms.; at term it was 1,000 grms. The laity could diagnose a pregnancy in an advanced stage; but in its beginning the diagnosis of pregnancy was very difficult. There was a multiplicity of signs of pregnancy, but not one of them was decisive before the third month. Dr. Jacobson said that he felt indebted to Dr. Ladinski for having brought forward a new sign which was decisive of early pregnancy, and if it proved such Dr. Ladinski would have earned great merit and deserve the gratitude of the whole profession.

Dr. Brooks H. Wells said that in 1884 Dr. Collyer and himself made the diagnosis of pregnancy by this same sign, but they had called it by other names. These signs, like others, were discovered, became popular, and were then forgotten. Then they were, as it were, rediscovered. Therefore, Dr. Wells objected to calling a sign by the name of an individual, but preferred to give it a descriptive name. He believed it was perfectly possible to diagnose pregnancy in certain cases as early as the fourth, the sixth or the eighth week. A number of cases had been positively diagnosed in the fifth and sixth week.

Dr. Herman L. Collyer said that he believed Hegar to be the first to discover or suggest this early sign of pregnancy and, in this country, Dr. Grandin wrote the first article on Hegar's sign, but he had added to that sign what Dr. Grandin had discovered himself but without taking the credit. Hegar's sign was merely the softening of the cervical tissue. Dr. Collyer called it an elastic enlargement at the fundus, as though a rubber ball had been shoved up the uterus. Dr. Dickinson had written an excellent article on this and gave an interesting description. In addition to the elastic enlargement, discoverable at four weeks, there was also a softening at the tip of the cervix. There was also beginning softening of the cervical tissue, but this was not so early as the elastic enlargement at the fundus. If the ovum was impregnated at the cornua, the elastic enlargement would be at that cornua of the uterus. It seemed to him that the uterus enlarged at the site of the ovum, where it was apt to remain. Dr. Collyer said there was another sign equally important, but only corroborative—the pulse sign of Janet of Paris; in this the pulse beats were the same whether the patient was standing or sitting.

Dr. William S. Stone said that at the Vanderbilt Clinic since September every man who had examined a certain woman said, "She is about four months pregnant." Dr. Stone had said the same thing only yesterday (March 27). Therefore, there was some uncertainty about this sign. He asked if this elasticity was felt just above the internal os and then called attention to the explanation of this softening occurring in Winter's book on "Gynecological Diagnosis." McDonald's sign depended upon the same anatomical condition as did Hegar's sign. There was one thing that they could rely upon, namely, the asymmetrical uterus in the early part of pregnancy.

Dr. F. A. Dorman said there were cases in which every sign would fail, and the more one examined these cases the less willing would he be to swear absolutely that a woman was pregnant at the sixth week. The sign offered by Dr. Ladinski was a valuable one and, from the strong statements made, he would study it more.

Dr. Ladinski said that he had been teaching the importance of this sign for fifteen years and that he had always told his students that the sign was *not* original with him. He had had a splendid opportunity to examine for this sign at the Beth Israel Hospital, where on some days as many as seventy or eighty women were examined, and the sign was found without any questioning of the patient. He believed that the sign was infallible.

SECTION ON PEDIATRICS.

Stated Meeting, Held March 14, 1907.

Dr. Godfrey R. Pisek in the Chair.

Angioneurotic and Other Essential Edemas in Children.—Dr. Herman Schwarz described in brief some of the theories as to the causation of general and local edema. The works of Weltzer and Inincke were mentioned. He then went on to the clinical portion of this paper. The first case was one of general edema following scarlet fever, without albumin or casts in the urine. The edema occurred in the second week of the disease, during what

appeared to be a normal convalescence, it lasted about two weeks, and at no time was there albumin in the urine. The patient made a perfect recovery. The second case was one of giant urticaria following scarlet fever after the exhibition of quinine. There was swelling of the hands, face, and feet, occurring one after the other and disappearing rapidly. The urine was and has been perfectly normal. The third case was one of general edema following erysipelas neonatorum. Here the signs of the erysipelas had almost entirely disappeared, and it was only with the help of the previous history and the condition of the skin (bleb-desquamation, etc.) that the cause of this edema was discovered; urine negative—recovery in two weeks. Finkelstein and Hensch mention similar cases. The fourth case was one of general edema, following gastroenteritis. The uranalysis was negative. This case was interesting inasmuch as the child was given a mixture of fennel tea and barley water for three weeks. During this time it had no edema. Then it was put upon a mixture of equal parts of milk and barley water—seven bottles a day and a pinch (10 grs.) of salt in each bottle—in other words, the child received 70 grains of NaCl in 24 hours. After being on this mixture for three days the edema began to appear. Very probably the atrocious mixture of fennel tea and barley water and the resulting poor condition of the child had a great deal to do with the edema, yet in the light of our new theories as to the connection between the retention of chlorides and the appearance of edema, the large amount of salt taken by the baby might also be taken into consideration and probably be an exciting factor in this case. The fifth and last case was one of angioneurotic, or better, acute circumscribed edema, in a girl of eleven years. The attacks had been coming since her sixth year—face, hands, and feet, were involved at different times. She had had edema of the glottis twice during the past three years. With and without these swellings there were attacks of abdominal pain and vomiting. These attacks lasted twelve to twenty-four hours. There was no family history. Neither diet nor drugs had had any effect in diminishing the frequency or severity of the attacks.

Dr. Attilio Caccini reported the case of a girl, seven years old, who was taken ill and developed general anasarca, and died without presenting any kidney lesions so far as the urinary findings were concerned. The examination of the blood showed 7,000,000 red cells, and 120 per cent. hemoglobin. This was a case probably of angioneurotic edema. He said that he had at present a boy, twelve years old, under observation, whose attacks came on with the slightest disturbances, as of the tonsils or the intestines. There was much itching, especially of the head, neck, and chest. After two or three days lumps would appear on his forehead, then all over the head, their size being about that of half an orange. These lumps at times made him appear as a monster. Another case he had seen was that of a boy who was suddenly taken with great dyspnea and, in spite of intubation and tracheotomy, died. At autopsy nothing was found to account for the death except the edema of the larynx. He related the history of another case of a superintendent of a hospital who complained of toothache, and who was advised to go to a dentist. For some reason he was given phenacetin, walked from the hospital, and in fifteen minutes dropped dead on the sidewalk. His eyes were so swollen that he was hardly recognizable.

Dr. Louis Curtis Ager of Brooklyn believed that in the first two cases reported by Dr. Schwarz, the so-called angioneurotic edema following scarlet fever, there might have been some kidney lesions behind to account for the edema which had not been recognized. He called attention to Dr. Cabot's long series of investigation in relation to the urinary findings in the various forms of nephritides, and how careful one should be to exclude nephritis because of negaitve urinary findings. A large number of cases that came to autopsy showed kidney lesions when there were only negative urinary findings during life. One should bear in mind too that all sorts of irritating conditions of the skin were produced in children under one year of age by slight reactions or mild infections. Again, in true angioneurotic edema there was apt to be an eosinophilia. Most of these cases he thought were due to some toxic condition.

Dr. Godfrey R. Pisek recently was called to see a case of primary edema of the lungs. Under large doses of strychnine and adrenals by the mouth, the condition cleared up. The child was two and a half years old.

Dr. George Dow Scott reported the case of a child with acute bronchitis and edema of the larynx. The patient quickly became moribund and died.

Dr. Eli Long said that many of the cases of edema were due to nephritis, whether anything was found during life in the urine or not. In those poorly fed, in marasmatics, edema appeared sooner or later. Also, it was seen in children with congenital specific disease. He thought that angioneurotic edema should be placed in a class by itself, where there was no etiological factor. Dr. Long told of the case of a child fed on condensed milk; when placed on proper food the edema cleared up and a good recovery followed.

Dr. E. H. Bartley of Brooklyn asked for a distinction between angioneurotic edema and giant urticaria. He reported the failures made in attempting to cure a man, forty years old, who had what was diagnosed as giant urticaria or hives.

Dr. Schwarz said that he had tried to find a distinction between giant urticaria and angioneurotic edema, but had not been successful. Cases of urticaria, however, were almost always associated with some form of digestive disturbance. Packard had mentioned a case of urticaria associated with asthma. Dr. Schwarz could not find any mention of the violent attacks of colic, vomiting, or diarrhea in angioneurotic edema, as occurred in some forms of urticaria. Light attacks of edema following gastrointestinal disturbance he believed to be quite common, and they disappeared very rapidly on change in diet. The cases he reported were not very common, especially that one of erysipelas neonatorum. In the case of enteritis the question arose whether or not the salt given might not have had some effect in the production of a nephritis.

The Indications for and the Technique of Paracentesis of the Drum Membrane.—Dr. John McCoy read this paper. He first took up the anatomical considerations, believing that for the intelligent understanding of the causes and effects of suppuration of the middle ear, it was absolutely essential to have a comprehensive knowledge of the anatomy of this region. It was of special interest to note that the roof or vault of the tympanic or middle ear cavity was formed by the osseous lamina of the squama and had lying above it a portion of the brain of the middle fossa. In infants the petrosquamous suture was still patent, and there was an intimate relation of the blood-vessels of the dura and of the middle ear. This explained why so many infants manifested meningeal symptoms when they had a suppuration in the middle ear, and why it was so easy for them to develop a meningitis. The following points should be looked for in a normal drum: (1) A lustrous pearl-gray, slightly concave, membrane. (2) A bright reflex of light at the anterior inferior quadrant of this membrane. (3) A prominent white projection about the size of a small pin head situated in the center of the upper portion of the drum. (4) Two whitish bands running from this prominent white spot in a horizontal direction, one to the anterior circumference, and the other to the posterior circumference of the drum. These were known as the anterior and posterior folds, and marked the dividing line between the relaxed and the tense portion of the drum. Aside from traumatic rupture of the drum and infection of the middle ear from the external auditory

canal, the cause which led in the great majority of cases to a suppurative inflammation of the middle ear cavity, was an extension of an inflammation from the nose or pharynx through the Eustachian tube. Occasionally, however, the inflammation in the middle ear was primary. It had been demonstrated that streptococci were found in the healthy middle ear free from all inflammation. The diseased conditions which conduced to an involvement of the middle ear through the Eustachian tube were such as occurred in any of the exanthemata, especially scarlet fever, diphtheria, measles, pneumonia, and influenza. It frequently followed the ordinary catarrhal cold, and it might follow the introduction of fluids through the nose into the Eustachian tube. Following the changes to be seen in the drum membrane from the inception of the inflammatory process to the time when it became necessary to incise it, there would be seen, first, that the drum was losing its luster; following this there would take place a congestion in the upper relaxed portion of the drum which would gradually spread over the whole drum. Then would be noticed a slight bulging of outward, usually in the upper posterior portion of the drum. It was then time to incise it. In examining an ear for this condition it was well to bear several points in mind, as follows: (1) In infants, the auricle should be drawn downward and backward to separate the inferior from the superior wall of the meatus. In older children the auricle should be drawn upward and backward. (2) One should be prepared with an applicator and cotton to remove particles either of wax or dead epithelium or medicaments, such as oil or other substances that might have been introduced into the canal. (3) One should remember that instead of seeing a red bulging drum, one might see a drum of a dull whitish-gray color. This was due to necrosis of the epithelium of the dermal layer of the drum, and if this was gently swabbed it would come away and reveal the congested drum beneath. (4) It was always well to examine both ears. Many children gave no subjective symptoms of ear trouble. Earache was frequently produced by decayed teeth, without any change in the ear whatsoever. Fever was really the only constant symptom, and in the absence of all other physical signs to explain it, the ears should always be examined. Prior to a paracentesis the external auditory canal should be sterilized by irrigation with 1-2000 bichloride solution. The hands should be sterilized and the instruments boiled. In infants it was better not to give an anesthetic. For older children nitrous oxid gas was safe and efficient. Beginning at the lower posterior segment a small straight, or sickle-shaped knife should be plunged into the membrane, and this should be carried directly up to the superior margin of the drum and in withdrawing the incision should be carried outward for about one-eighth of an inch. This gave free drainage to the whole cavity; the loss of blood and fluid relieved the pressure and pain; there was more rapid healing of the cut surface than if a small opening was made or a spontaneous perforation was allowed to take place; there were also minimized the chances of mastoid involvement. The dangers of paracentesis were that if too much force was used, or if the operator did not know the direction in which his knife was cutting, he might enter some of the structures he had enumerated; cases had been reported where the jugular bulb, the carotid artery, or the internal ear had been entered.

Dr. Louis C. Ager, Dr. Herman Schwarz, Dr. Eli Long, and others discussed this paper.

Dr. McCoy closed the discussion.

Chicago Medical Society.

At a regular meeting held February 20, 1907, there was a symposium on Influenza. Dr. Joseph L. Miller discussed the etiology, diagnosis, symptoms, and treatment, with special reference to the cardiac, pulmonary, and gastrointestinal complications. Dr. Wm. G. Stearns pointed out the complications affecting the nervous system, and discussed their treatment. Inasmuch as the primary effect of the influenzal toxin upon the nervous system is always irritative, he said opium and bromides were found to be of the greatest use. Calomel and soda, if given with opium, would aid the diuretic and hepatic stimulation. Where the wet pack was properly used, its effect was most beneficial. Dr. William Lincoln Ballenger, in discussing the treatment of acute mastoiditis due to scarlet fever, diphtheria, and influenza, presented the following conclusions: (1) The reaction of inflammation consisted of an increased hyperemia, increased cell nutrition (increased resistance), and an increased migration of leucocytes. (2) The reaction of inflammation was an increased physiological activity for the purpose of eliminating certain noxious irritants, notably bacteria and their toxins, from the tissues. (3) In acute inflammations the reaction of inflammation was usually inadequate to accomplish the destruction of the bacteria and their toxins within a short time. (4) The reaction being inadequate, it should be promoted, and experience had shown such promotion to be effective. (5) In acute otitis media incision of the ear drum promoted the reaction of inflammation in the quickest and surest way, and thus often prevented destructive processes of this important organ. Incision also provided for adequate drainage, and thus favored the elimination of the bacteria, and raised the resistance of the tissues. In acute mastoiditis, leeching, in addition to incision of the ear drum, if spontaneous perforation had not already occurred, was the best available means of promoting the reaction of inflammation. Heat followed by a dash of cold water was another effective means of promoting the reaction of inflammation. Dr. H. Manning Fish discussed the complications of influenza resulting from infection of the nasal accessory sinuses. The author said that the cerebral and ocular symptoms which either accompanied influenza or appeared in a patient with a history of influenza should suggest a sinus disease. Certain symptoms, as vertigo, cephalalgia, optic neuritis, and other ocular lesions that were often attributed to circumscribed meningitis, or to a brain tumor, might be due to a sinus disease. A recurrent inflammatory condition in the eye that was aggravated by a cold, or was worse in the winter months, suggested a chronic sinusitis. In all cases with cerebral symptoms the accessory sinuses should be examined as well as the ear. Sinus disease should not be excluded on account of a negative nasal finding, or by the absence of pain, either spontaneous or on pressure. In the discussion Dr. Theodore Tieken said he had noticed irritable bladder in many cases of influenza, and in these microscopic examination disclosed a catarrhal cystitis. He mentioned a young girl, with influenza, who urinated every ten or fifteen minutes. Dr. Adolph Gehrmann referred to the wide distribution of the bacillus of influenza, saying it was relatively easy to find on mucous surfaces and in pus that had recently formed. Apparently this bacillus died when the pus remained for any length of time, and we probably had the effect of the influenzal bacillus through its toxin from disintegration. He had found this bacillus on every mucous membrane in the body. Dr. Aemerin W. Baer deprecated the frequent use of coal tar preparations in treating cases of influenza, believing that nothing was more debilitating to sick patients than the addition of such drugs to their already diseased condition.

Nervous Lesions Accompanying Exophthalmic Goiter.—Poggio describes the autopsy on a woman [illegible] years, suffering from exophthalmic goiter, who died in coma. Except for slight cardiac hypertrophy the organs were normal. The central nervous system was congested and in the medulla, pons, the floor of the fourth ventricle and in the nuclei of several of the cranial nerves there were degenerative changes.—*Clinica Medica Italiana.*

Surgical Suggestions.

Gunpowder Marks. An ointment of beta naphthol, 10; sulphur, 45; lard, 24; and green soap, enough to make 100 parts, is useful in removing gunpowder not too deeply situated in the skin. It must be employed cautiously, however, to avoid a destructive dermatitis.—*American Journal of Surgery.*

Epididymitis.—Johnson reports excellent results following the application of adhesive strips, which latter are so placed that they form a sling. The technique follows: After shaving the parts, the patient being in dorsal decubitus, a strip of zinc oxide plaster two and one-half to three inches wide is applied to the lower abdomen, from one and one-half to two inches from the median line; the strip, face upward, is taken around and under the scrotum, elevating the testicles to a level at least as high as the penopubic angle, and forming, as it were, a sling; the other end of the strip is passed upward on the opposite side of the median line of the abdomen. A second strap is similarly applied, and adjusted about the scrotum; a few short straps are placed across the anterior portion of the scrotum. Johnson emphasizes the fact that there should be no pressure made on the inflamed tissues.—*St. Louis Courier of Medicine.*

Removal of Adenoids.—The following position of the patient is recommended by Holmes in the *Laryngoscope:* The patient, when thoroughly anesthetized, is placed on his left side on an operating table, the foot of which is slightly elevated. The left arm and shoulder of the patient are drawn back, so that the former lies on the table behind the patient, and the right shoulder is drawn back by an assistant with a view to increasing the breathing space and at the same time steadying the child. The face is brought even with the edge of the table or slightly over the edge, and the operator, equipped with an electric forehead mirror and seated on a stool of medium height, performs the operation in the usual way. By this method of performing the operation, first, the position of the patient adds nothing to the ordinary dangers of the anesthetic; the force of gravitation does not add to the burden of the heart; the neck is straight; the respiration is not embarrassed by "embracing" the chest or "fixing" the arms or by the pharynx filling with blood which is likely to find its way into the windpipe. Second, the position of the head is such that all of the hemorrhage finds its way out of the nose, or out of the mouth. In this way the field of operation is kept clear so that the operator can at all times see the posterior pharyngeal wall or can easily clear it with a wad of cotton on a sponge holder, and can detect and remove any shreds that tend to make the operation imperfect; and, third, the amount of blood lost can be accurately appreciated.—*Fort Wayne Medical Journal.*

Rectal Hemorrhage.—Mason says that when blood is passed from the bowel it is nearly always due to some form of internal hemorrhoids, generally of the capillary variety. Well-formed venous tumors, when constricted by the internal sphincter muscle, often bleed profusely, due to the blood being forced out through a small opening in the tumor wall. In either case the blood is lost at stool. If the amount is small and is noticed immediately following a bowel movement and is accompanied by pain of a lacerating, aching character, it probably comes from a fissure. If it comes on independently of a bowel movement it may be due to a carcinoma or ulcer. If it comes on suddenly and has not been noticed before, it may be due to a foreign body.—*American Journal of Clinical Medicine.*

Ankylosis of the Elbow.—Hoffman has successfully transplanted a flap of periosteum from the tibia to the freshened surfaces of the humerus and ulna in a case of ankylosis at the elbow and in this way secured a satisfactory result.—*Archiv für klinische Chirurgie.*

Milk as a Hemostatic.—Salt states that in a number of cases he has found that milk given by rectum served as a hemostatic in cases of uterine, gastric, and pulmonary hemorrhage. From eight ounces to two pints of milk, to which a little salt had been added, were injected. Salt explains the effect by referring to the fact that milk contains a number of substances, such as calcium and iron salts, that are ordinarily used as hemostatics, as well as the products of the degeneration of leucocytes. When the milk is given by mouth the digested processes interfere with this hemostatic action.—*Therapeutische Monatshefte.*

Retroversion of the Uterus.—The following modification of the many similar operations for this condition is suggested by Liepmann. The peritoneum at either side of the median incision is buttonholed and through each of the small openings a loop of the corresponding round ligament is drawn and fixed by a suture passing through the fascia of the rectus muscle.—*Zentralblatt für Gynäkologie.*

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

BOARD OF MEDICAL EXAMINERS OF THE STATE OF NEVADA.

August 7, 8, and 9, 1905.

ANATOMY.

1. What valves guard the auriculoventricular opening in the left side of the heart? Those in the right?
2. Between the cartilages of what ribs would you locate the apex of the normal heart? What is the average weight of the heart of an adult male?
3. What is the average weight of the brain in the adult male? In the adult female?
4. Name the three principal arteries of the forearm.
5. Of what artery is the nutrient of the tibia a branch?
6. Describe a sesamoid bone, its development, and function. Name the largest in the body.
7. What muscles are attached, wholly or in part, to the trochanter major?
8. Name the nerve that supplies the tongue with the sense of taste; of sensation; of motion.
9. Name the three muscles of the tibiofibular region (superficial) that form the calf of the leg.
10. Name the ligament implanted near the center of the head of the femur.

PHYSIOLOGY.

1. Describe a cardiac cycle, and give the phenomena attending it.
2. Describe the reflex centers.
3. Describe the phenomena of blood clot.
4. What is the function of bile?
5. What is the normal ratio of heart pulsations to respiration in a healthy adult?
6. Give the physiological cause of sleep.
7. What is the function of the cerebellum?
8. Give a brief description of the portal circulation.
9. Give principal events in gastric digestion.
10. Define blood pressure.

PATHOLOGY.

1. Give the pathology of arteriosclerosis.
2. What diseases are attended with ulceration of the intestines?
3. What diseases are attended with cardiac hypertrophy?
4. Describe pus, and give its essential elements.
5. Differentiate fatty degeneration and fatty infiltration; give cause of each.
6. Describe briefly the pathological changes taking place in acute lobar pneumonia.
7. Describe lipoma, and give its most frequent locations.
8. State the most important sequel of diphtheria, and describe to what extent it may occur.
9. What is the significance of hyaline casts in urine? Of granular casts?
10. Give pathology of embolus; of thrombus.

BACTERIOLOGY.

1. Give Koch's rules in regard to bacterial cause of diseases.
2. Describe the Klebs-Löffler bacillus.
3. Name four pathogenic bacteria that do not stain by Gram's method.
4. Describe the Widal serum reaction.
5. What is the commonest microorganism found in empyema?

MATERIA MEDICA AND THERAPEUTICS.

1. Give the adult dose of three opium preparations. Name its principal alkaloids.
2. Name three mercurial preparations. Give dose and use of each.
3. Name five emetics with dose of each.
4. Name two drugs incompatible with tannic acid. Give reasons.
5. With what preparations should the iodides *not* be combined?
6. Why should pepsin and pancreatin not be used together?
7. When is turpentine contraindicated?
8. From where are the following alkaloids obtained? Quinine, strychnine, physostigmine, hydrastin, atropine.
9. Outline treatment of a case of acute pneumonia.
10. Outline treatment of a case of typhoid fever.

CHEMISTRY AND TOXICOLOGY.

1. What is a mechanical mixture? A chemical compound? Give three examples of each.
2. Describe briefly the three acids most used in laboratory.

3. State the occurrence and properties of oxygen, hydrogen, and nitrogen.
4. State the occurrence and properties of arsenic, mercury, and iron.
5. Describe respiration from a chemical point of view.
6. Describe the toxic effect of carbolic acid. Outline treatment for same.
7. Give symptoms of and antidote for arsenic poisoning.
8. Give symptoms of and outline treatment for a vegetable poison.
9. Name antidote for nitrate of silver, opium, phosphorus, corrosive sublimate, wild parsnip.
10. Give inventory for contents of antidote bag.

THEORY AND PRACTICE OF MEDICINE.

1. Give the symptoms of typhoid fever in first, second, third, and fourth weeks, and treatment of same.
2. Give diagnosis, pathological anatomy, symptoms, and treatment of chronic parenchymatous nephritis.
3. Give symptoms and treatment of cerebrospinal meningitis.
4. Give stages and symptoms of acute lobar pneumonia, and treatment.
5. What are the symptoms, complications, and differential diagnosis of acute articular rheumatism and treatment?
6. What are the causes of, morbid anatomy, symptoms and treatment of rickets?
7. Give differential diagnosis of chronic gastric catarrh, gastric ulcer, and gastric cancer.
8. Give the forms of endocarditis, pathological anatomy, and physical signs.
9. Give definition, etiology, symptoms, complications, prognosis, and treatment of erysipelas.
10. Give the causes and symptoms of pneumothorax.

OBSTETRICS.

1. What is tubal pregnancy? Differentiate it from normal pregnancy. What are the three greatest dangers to the mother in tubal pregnancy?
2. What foramen unites the right and left auricles in the fetal heart?
3. In twin births how many placentas are there?
4. What membranes invest the fetus? Define their relations to it from within outward.
5. What veins carry arterial blood in the fetus?
6. What are the two most reliable diagnostic indications of abortion? How would you treat a case of threatened abortion?
7. What position does the uterus assume during the first three months of pregnancy?
8. What is the average period of pregnancy, computed by days? What were the extremes that legitimized a child under the Code Napoleon?
9. Diagnose a placenta previa. How would you treat such a case?
10. What are the most grave gynecological diseases to anticipate after delivery?

GENITOURINARY DISEASES.

1. Give differential diagnosis of anterior and posterior urethritis, complications of each, and write six prescriptions for treatment, three internal and three local.
2. What are the causes of orchitis, and give treatment of same.
3. Give treatment for gleet.
4. Describe a case of gonorrheal rheumatism, give causes, treatment, and prognosis.
5. Give history and description of syphilitic dermatitis.
6. Make differential diagnosis of hard and soft chancre and treatment of each.
7. Give causes, symptoms, and treatment of organic urethral stricture.
8. What is syphilitic dactylitis, the varieties, and tissues involved in each variety?
9. Describe the general course of syphilis, giving stages, symptoms, and treatment of each stage.
10. Give causes, symptoms, prognosis, and treatment of pyosalpinx.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

BOARD OF MEDICAL EXAMINERS OF THE STATE OF NEVADA

August 7, 8, and 9, 1905.

ANATOMY.

1. The mitral or bicuspid valve, on the left side; the tricuspid valve, on the right side.
2. Between the fifth and sixth, on the left side. Average weight is ten to twelve ounces.
3. In the male, forty nine ounces, in the female, forty-four ounces.
4. The radial, the ulnar, and the posterior interosseous.
5. The posterior tibial.
6. Sesamoid bones are cartilaginous in early life, but later become osseous. They are developed in the tendons of muscles at points where these latter are exposed to pressure upon the parts over which they glide. Their function is to increase the leverage of the muscles. The largest sesamoid bone in the body is the patella.
7. Gluteus medius, gluteus minimus, pyriformis, obturator externus, obturator internus, gemellus superior, gemellus inferior, and quadratus femoris.
8. The tongue is supplied with the sense of *taste* by the chorda tympani and the glossopharyngeal nerves; of *sensation*, by the lingual branch of the inferior maxillary division of the fifth cranial nerve; of *motion*, by the hypoglossal nerve.
9. The gastrocnemius, soleus, and plantaris.
10. The ligamentum teres.

PHYSIOLOGY.

3. When blood is withdrawn from the blood-vessels of the living body, it first becomes viscid, then sets, and is converted into a jelly-like mass. This is due to the formation of fibrin. The jelly contracts forming the clot; and at the same time the serum is squeezed out from the clot. Various circumstances and conditions will hasten or delay the process of coagulation. In man, the blood generally becomes viscid in from two to three minutes; it forms the jelly-like mass in from five to six minutes; a few minutes later the serum begins to appear; and the whole process is completed in from twenty-four to thirty-six hours. The clot then floats on the serum. The process is thus summed up by Halliburton: In the plasma a proteid substance exists, called Fibrinogen. From the colorless corpuscles a nucleo-proteid is shed out, called Prothrombin. By the action of calcium salts prothrombin is converted into fibrin ferment, or Thrombin. Thrombin acts on fibrinogen in such a way that two new substances are formed: one of these is unimportant and remains in solution; the other is important, viz., Fibrin, which entangles the corpuscles, and so forms the clot.
4. The functions of the bile are: (1) to assist in the emulsification and saponification of fats; (2) to aid in the absorption of fats; (3) to stimulate the cells of the intestine to increased secretory activity, and so promote peristalsis, and at the same time tend to keep the feces moist; (4) to eliminate waste products of metabolism, such as lecithin and cholesterin; (5) it has a slight action in converting starch into sugar; (6) it neutralizes the acid chyme from the stomach, and thus inhibits peptic digestion; (7) it has a very feeble antiseptic action.
5. About four or five heart pulsations to one respiration.
6. "There are several hypotheses as to the causation of sleep. It has been attributed to cerebral anæmia; to chemical changes in the brain cells or neurons, such as an exhaustion of their intramolecular oxygen, or an accumulation of fatigue products; to a contraction of the dendritic processes, and a consequent break in the transmission of nervous impulses; to an expansion of the neuroglial cell processes insulating the nerve cell processes, and producing the same effect; and to a purely psychological condition, namely, loss of consciousness apart from any physical or chemical change. This last explanation is simply a cloak for our ignorance. The most probable hypothesis is that of an altered metabolism of the cerebral cells dependent upon exhaustion and diminished influx of stimuli." (Allbutt's *System of Medicine*.) Two new theories have recently been promulgated. One claims that sleep is due to an internal secretion of the pituitary gland, whereas the other makes it depend upon the phenomena of osmosis.
7. Coordination and equilibrium.
8. The principal events in gastric digestion are the conversion of the proteids into proteoses and peptones, which are more soluble and diffusible. Starches are [illegible], and fats are not altered chemically.
10. Blood pressure is the pressure on the blood. Due to the ventricular systole, the elasticity of the walls of the arteries, and the resistance of the capillaries.

PATHOLOGY.

2. Typhoid fever, tuberculous enteritis, dysentery, chronic nephritis, extensive burns, syphilis, cancer, enteritis in children, actinomycosis, and anthrax.
3. Chronic nephritis, emphysema, tuberculosis, aortic stenosis, aortic regurgitation, mitral regurgitation, chronic myocarditis, arteriosclerosis, gout, lithemia, pericardial adhesions, exophthalmic goiter, hysteria, lead poisoning, and syphilis.

4. Pus is a thick, creamy fluid, alkaline in reaction, with a specific gravity of about 1030, and containing from eighty to ninety per cent. of water. On standing it separates into two layers, the upper part being fluid, and consisting of serum, a little proteid matter and liquefied tissue; the lower, or solid part, contains dead and living pus corpuscles, fatty and granular débris, and sometimes microorganisms, and a few red blood cells.

5. In *fatty infiltration* the tissues contain fat brought from without; there is no change in the cell protoplasm, and such damage as the tissue undergoes is due to the mechanical pressure caused by the fat.

In *fatty degeneration* the cell protoplasm undergoes change; the fat is in the cells, and not between them.

Fatty infiltration may be due to obesity, lack of exercise, overeating, or drinking, carcinoma, diabetes, chlorosis, fracture, or disease of bones, or it may be hereditary.

Fatty degeneration may be caused by poisoning (chiefly by phosphorus, lead, mercury, or arsenic), anemia, prolonged fevers, diabetes.

7. A lipoma is a benign tumor composed of fatty tissue. It is roundish, soft, generally circumscribed and encapsulated, and lobulated. On section the fat is seen to be divided by septa of fibrous connective tissue. It is of slow growth, and generally appears in adult or middle life, but may also appear in childhood.

The most frequent locations are the subcutaneous tissue of the shoulders, limbs, back, and buttocks, the mammary gland, and kidney.

8. Paralysis is the most important sequel of diphtheria. It is due to toxic neuritis, and is found as a rule during convalescence, and occurs in from about ten to fifteen per cent. of all cases. It may follow either a mild or a severe attack of diphtheria; and the pharynx, uvula, muscles of the eyes, face, one or both extremities, respiration, or heart may be affected.

9. "*Hyaline casts* are common to all diseases and disturbances of the kidney, and not pathognomonic of any one abnormal condition. They are, however, predominant in the sediment in cases of chronic interstitial, chronic diffuse nephritis, amyloid infiltration, and in passive hyperemia; while their relative proportion is much smaller in comparison with the other forms of casts present in active hyperemia, acute nephritis, and subacute glomerular nephritis."

"*Finely granular casts* are found in every disease or disturbance of the kidney; they, therefore, cannot be considered pathognomonic of any one disease or class of diseases." (Ogden, *On the Urine.*)

BACTERIOLOGY.

1. Koch's rules in regard to the bacterial cause of disease are: (1) the microorganism must be found in the tissues, blood, or secretions of a person or animal sick or dead of the disease; (2) the microorganism must be isolated and cultivated from these same sources; it must also be grown for several generations in artificial culture media; (3) the pure cultures, when thus obtained, must, on inoculation into a healthy and susceptible animal, produce the diseases in question, and (4) the same microorganisms must again be found in the tissues, blood, or secretions of the inoculated animal.

2. The Klebs-Loeffler bacillus is a short rod, about three to six microns in length, and about a half to one micron in breadth; the extremities may be rounded or clubbed. The bacilli are slightly curved, and may occur singly, in pairs, or in groups; they are non-motile, have no flagella, are aerobic, and contain granules which take on a deeper stain. The bacillus stains with the analine colors, by Gram's method, and with Loeffler's alkaline methylene-blue.

3. *Bacillus coli communis, Spirillum choleræ asiaticæ,* Friedlander's *Bacillus pneumoniæ,* and Obermeier's spirochete of relapsing fever.

4. The Widal serum reaction "depends upon the fact that serum from the blood of one ill with typhoid fever, mixed with a recent culture, will cause the typhoid bacilli to lose their motility and gather in groups, the whole called 'clumping.' Three drops of blood are taken from the well-washed aseptic finger tip or lobe of the ear, and each lies by itself on a sterile slide, passed through a flame and cooled just before use; this slide may be wrapped in cotton and transported for examination at the laboratory. Here one drop is mixed with a large drop of sterile water, to redissolve it. A drop from the summit of this is then mixed with six drops of fresh broth culture of the bacillus (not over twenty-four hours old) on a sterile slide. From this a small drop of mingled culture and blood is placed in the middle of a sterile cover-glass, and this is inverted over a sterile hollow-ground slide and examined. . . . A positive reaction is obtained when all the bacilli present gather in one or two masses or clumps, and cease their rapid movement inside of twenty minutes." (From Thayer's *Pathology.*)

5. The microorganisms most commonly found in empyema are the *Streptococcus pyogenes* and the pneumococcus; others commonly found are the *Staphylococcus pyogenes* and the tubercle bacillus.

MATERIA MEDICA AND THERAPEUTICS.

1. Pulvis Ipecacuanhæ et Opii, dose gr. vijss. Acetum Opii, dose ɱviij. Tinctura Opii, dose ɱviij. Vinum Opii, dose ɱviij. The principal alkaloids are: Morphine, codeine, thebaine, narcotine, papaverine, pseudomorphine, and narceine.

2. Hydrargyri Chloridum Corrosivum, dose gr. 1/20; used chiefly, externally, as an antiseptic and parasiticide. Hydrargyrum cum Creta, dose gr. iv; used chiefly as a mild laxative, an alterative, and antisyphilitic. Hydrargyri Subsulphas Flavus, dose gr. ij to iv; used as an emetic.

3. Apomorphinæ hydrochloridum, dose gr. 1/16, hypodermatically; or gr. 1/10, by mouth. Zinci Sulphas, dose gr. xv to xxx. Cupri Sulphas, dose gr. iv. Alumen, dose a teaspoonful. Antimonii et Potassii Tartras, dose gr. j to ij.

4. Ferric Salts and Alkaloids. With the former, ink is formed; with the latter, an insoluble precipitate.

5. With mineral acids, alkaloids and their salts, metallic salts, and ammonia.

6. Because pepsin requires an acid medium in which to exercise its powers, and pancreatin requires an alkaline medium.

7. In diseases of the kidneys, cardiac hypertrophy, hemorrhage, and plethora.

8. Quinine, from Cinchona. Strychnine, from Strychnos Nux Vomica, and Strychnos Ignatia. Physostigmine, from Physostigma (Calabar bean). Hydrastin, from Hydrastis (Golden Seal or Yellow Puccoon). Atropine, from Atropa Belladonna.

CHEMISTRY AND TOXICOLOGY.

1. *A chemical compound* is a substance made of two or more elements, chemically united, in definite proportions. Examples: water, sulphuric acid, iodoform.

A mechanical mixture is the product obtained by uniting into a more or less homogeneous whole two or more substances, whether elements or compounds, in any proportion, and without any chemical union. Examples: air, sugar adulterated with sand, salt in water.

2. *Hydrochloric acid:* when pure this is a colorless gas with a sharp, penerating, and irritating odor; it is very soluble in water; it does not support combustion nor does it burn in air; it is very corrosive. The ordinary hydrochloric acid is a solution of this gas in water, and is found in three varieties: the commercial, the pure, and the dilute acids.

Sulphuric acid is a colorless, thick, oily liquid, odorless, very corrosive; has a great tendency to unite with water; it chars organic matter.

Nitric acid is a colorless or faintly yellow liquid, has a sour taste, a suffocating odor, and is very corrosive. It is a strong oxidizing agent, and stains animal tissues yellow.

3. *Oxygen. Occurrence:* free in the air and in combination in water, rocks, minerals, etc. It is more abundant than any other element, forming about forty per cent. of the total weight of the earth. *Properties:* It is a colorless, odorless, tasteless gas, heavier than air, slightly soluble in water, has an intense affinity for other elements, combining with almost all of them except fluorine. It is necessary to life, and is a supporter of combustion.

Hydrogen. Occurrence: free in volcanic gases, in fire damp, and the gases of the intestines; and in combination in water, all acids and in many organic compounds. *Properties:* A colorless, odorless, tasteless gas, the lightest known substance; it has a great affinity for oxygen; it supports neither combustion nor respiration; it is a necessary constituent of all acids; the gas will burn with a pale blue flame, giving little light, but an intense heat.

Nitrogen. Occurrence: free in the air, in combination in nitrates, ammonia, and in many organic substances. *Properties:* A colorless, odorless, tasteless gas, it neither burns nor supports combustion nor respiration, it has no tendency to unite with other elements.

4. *Arsenic. Occurrence:* free in very small quantities; chiefly in combination with sulphur as realgar, orpiment, and mispickel. *Properties:* It is a gray solid, is easily powdered, if pure it is odorless and tasteless; it is a good conductor of electricity, and is easily oxidized. There are four atoms to the molecule of arsenic.

Mercury. Occurrence: Usually found in combination with sulphur, as cinnabar. *Properties:* It is liquid metal, is slightly volatile, the molecule contains only one atom; it unites directly with chlorine, bromine, and iodine; it is a necessary constituent of amalgams.

Iron. Occurrence: free, in small quantities only; in

combination as oxides, carbonates, or sulphides, in hematite, magnetic iron, spathic iron, pyrites, etc. *Properties:* Pure iron is white and soft, and crystallizes in cubes or octahedra; it is unaffected by dry air at ordinary temperature; in damp air it is converted into iron rust (a hydrate of iron); at red heat it is oxidized. It is dissolved by the strong mineral acids.

6. *Symptoms:* "Those portions of the skin and mucous membrane which have been in contact with the poison are whitened and hardened. There are burning pains in the mouth, esophagus, and stomach, and vomiting; lowering of the pulse and temperature, contraction of the pupils, stupor, syncope, and collapse, terminating in death. The urine, clear and of the normal color when voided, becomes rapidly greenish, and finally dark olive-green or almost black." (Witthaus.)

Treatment: White of egg should be administered; also sodium sulphate, and the stomach should be gently washed out. Alcohol is said to be antidotal.

7. *Symptoms:* "In acute cases the symptoms usually begin in from twenty to forty-five minutes. Nausea and faintness. Violent, burning pain in the stomach, which becomes more and more intense, and increases on pressure. Persisting and distressing vomiting of matters, sometimes brown or gray, or streaked with blood, or green (Paris green). Purging. More or less severe cramps in the lower extremities."

In Chronic Cases: "Inflammation of the conjunctivæ, with intolerance of light. Irritation of the skin, accompanied by an eruption (eczema arsenicale). Local paralyses. Great weakness and emaciation. Exfoliation of the cuticle and falling out of the hair." (Witthaus.)

The *antidote* is freshly prepared ferric hydroxide.

9. The *antidote* for *nitrate of silver* is salt and water; for *opium*, there is no one substance which is a complete antidote, washing out the stomach with a dilute solution of potassium permanganate is the best treatment; for *phosphorus*, old French oil of turpentine; for *corrosive sublimate*, white of egg; for *wild parsnip*, emetics, lavage, and purgatives.

10. The following is mentioned in Potter's *Materia Medica*, etc.: Dialyzed iron, syrup or chloral, chloroform, spirits of chloroform, calcined magnesia, aromatic spirits of ammonia, oil of turpentine, acetic acid, tincture of digitalis, tannic acid, amyl nitrite, zinc sulphate, ipecacuanha, potassium bromide, potassium permanganate. Also a hypodermic syringe and solutions or pellets therefor of: morphine sulphate, atropine sulphate, apomorphine hydrochlorate, pilocarpine nitrate, strychnine nitrate. To the above should be added a stomach tube and a soft rubber catheter.

THEORY AND PRACTICE OF MEDICINE.

7. *Chronic gastric catarrh* is generally caused by indiscretions in diet, or by mental worry, it may occur at any time of life, and is characterized by pain in the epigastric region which generally comes on after eating; there is apt to be morning vomiting, the vomitus consisting of mucus with undigested particles of food; there is seldom hemorrhage; the stomach may be enlarged, and examination of the gastric contents shows free HCl diminished or absent, and the digestive ferments diminished.

Gastric ulcer is generally caused by injury or bacteria, is most apt to occur between the ages of twenty and forty-five; after eating there is pain localized in the stomach, vomiting occurs soon after eating, hematemesis is common, there is localized tenderness over the stomach, and examination of the gastric contents shows an excess of free HCl.

Gastric cancer does not usually occur before forty years of age, is more common in males, the pain is localized and constant, vomiting is copious and occurs some time after eating; the vomitus contains "coffee ground" material; hemorrhages are common; a tumor may be palpated, and examination of the gastric contents shows absence of free HCl and presence of lactic acid; severe anemia and cachexia are also present.

OBSTETRICS.

1. Tubal pregnancy is a pregnancy in which the ovum is arrested in the Fallopian tube and develops there instead of in the uterine cavity.

In differentiating this condition from a normal pregnancy the following signs and symptoms are of most reliance. "When extrauterine pregnancy exists, there are: (1) The general and reflex symptoms of pregnancy; they have often come on after an uncertain period of sterility. Nausea and vomiting appear aggravated. (2) Then comes a disordered menstruation, especially metrorrhagia, accompanied with gushes of blood, and with pelvic pain coincident with the above symptoms of pregnancy. Pains are often very severe, with marked tenderness within the pelvis. Such symptoms are highly suggestive. (3) There is the presence of a pelvic tumor characterized as a tense cyst, sensitive to the touch, actively pulsating. This tumor has a steady and progressive growth. In the first two months it has the size of a pigeon's egg; in the third month it has the size of a hen's egg; in the fourth month it has the size of two fists. (4) The os uteri is patulous; the uterus is displaced, but is slightly enlarged and empty. (5) Symptoms No. 2 may be absent until the end of the third month, when suddenly they become severe, with spasmodic pains, followed by the general symptoms of collapse. (6) Expulsion of the decidua, in part or whole. Nos. 1 and 2 are *presumptive signs;* Nos. 3 and 4 are *probable signs;* Nos. 5 and 6 *are positive signs.*" (*American Text-Book of Obstetrics.*)

The three greatest dangers to the mother are: hemorrhage, peritonitis, and death.

2. The foramen ovale.

3. If the twins are from two ova from separate Graafian follicles there will be two placentæ; if from two ovules from one Graafian follicle, there will be one placenta; if from a single ovule with two nuclei, there will be one placenta.

4. The membranes investing the fetus are, from within outwards, the amnion, the chorion, and the decidua.

5. The umbilical veins.

6. Hemorrhage and a dilated os.

Absolute quiet and rest in bed, with the head lowered, and in a darkened room. Nerve sedatives should be administered in large doses; opium is indicated, either laudanum in fifteen or twenty minim doses, or the extract of opium in suppository. After the cessation of the hemorrhage the patient should be kept in bed for one or two weeks.

7. Increased anteflexion and descent.

8. About 278 to 280 days.

The extremes that legitimatized a child under the Code Napoleon were 180 and 300 days.

10. "Tears of the perineum destroy the integrity of the pelvic floor and result eventually in rectocele, cystocele, hemorrhoids, and displacements of the pelvic organs. If the tear involves the sphincter ani, incontinence also results. Lacerations of the cervix retard or check involution of the uterus and predispose to endometritis, menorrhagia, displacements, eversion of the cervical mucous membrane, cystic degeneration, and malignant disease. Deep lacerations of the vaginal vault may open into the base of the broad ligaments, and in the majority of instances genitourinary fistulas are caused by traumatisms of labor. All lacerations are immediately dangerous on account of the increased liability to sepsis, while the remote results are generally due to interference with involution or the pelvic circulation and to the destruction of the normal supports of the pelvis." (Ashton's *Gynecology.*)

GENITOURINARY DISEASES.

1. "*The symptoms of acute anterior urethritis* are: An incubation period of twenty-four hours, a tickling or an itching sensation at the meatus, which is red, glazed, and often colored with grayish, opaline mucus; the discharge is scanty at first, but gradualy increases. At the end of three or four days the redness and congestion about the meatus increase and may cause edema, phimosis, and paraphimosis. Lymphangitis is present. The discharge becomes thick and purulent. Ardor urinæ, chordee, and frequent urination are now present. At this stage, when the urine is passed into two glasses, in the first glass the urine will be cloudy; in the second, clear. The symptoms just mentioned usually last for about four weeks, when they gradually abate.

"*The complications of acute anterior urethritis* are phimosis, paraphimosis, chordee, painful erections, penitis, lymphangitis, adenitis, balanitis, periurethral abscess, Cowperitis, hemorrhage, and preputial folliculitis.

"*Symptoms of acute posterior urethritis.*—The discharge decreases; the frequency of urination increases; vesical tenesmus may be present; there is considerable pain; hematuria, albuminuria, and retention of urine are also symptoms. When the urine is passed into two glasses, both specimens will be cloudy.

"*Complications of posterior urethritis* are prostatitis, seminal vesiculitis, inflammation of the cord, epididymitis, orchitis, cystitis, nephritis, pyelitis, abscess of the prostate, abscess of the kidney, peritonitis, uremia, retention of urine, gonorrheal rheumatism. The sequels are hypochondriasis, sexual neurasthenia, stricture, impotence, sterility, hyperesthesia, spermatorrhea, and melancholia." (Gould and Pyle's *Cyclopedia of Medicine and Surgery.*)

2. *Causes of orchitis:*—Traumatism, inflammation of the urethra, epididymitis, rheumatism, mumps.

Treatment:—Rest in bed, elevation of the parts, hot or cold applications, pain is to be relieved by opiates or leeches, lead water and laudanum should be applied, salines or cathartics are to be administered. Sometimes strapping

the testicle is of service; so too, is the application of ichthyol and lanolin.

6.

HARD CHANCRE.	SOFT CHANCRE.
First lesion of a constitutional disease, viz., syphilis.	A local disease.
Due to syphilitic infection.	Due to contact with secretion from chancroid.
Generally a venereal infection.	Always a venereal infection.
May occur anywhere on the body.	Nearly always on genitals.
Period of incubation never as short as ten days.	Period of incubation always less than ten days (generally about three).
Generally single.	Generally multiple.
Not autoinoculable.	Autoinoculable.
Secretion slight.	Secretion profuse and purulent.
Slightly or not at all painful.	Generally painful.
As a rule only occurs once in any patient.	May reoccur in same patient.
Buboes are painless and seldom suppurate.	Buboes are painful, and usually suppurate.

8. Syphilitic dactylitis is a specific gummatous infiltration of the tissues of the digits, occurring in the tertiary stage of syphilis. It tends to undergo necrosis and ulceration, or inflammation and subsequent pyogenic infection.

There are two varieties: (1) In which the subcutaneous fibrous tissues and the ligaments are involved; and (2) in which the periosteum and bone are specially affected.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE.	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION		
Alabama*	W. H. Sanders, Montgomery	Montgomery	May	1–6
Arizona*	Ancil Martin, Phoenix	Phoenix	July	1
Arkansas*	F. T. Murphy, Brinkley	Little Rock	July	9
California	Chas. L. Tisdale, Alameda	San Francisco	April	16
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver	July	2

THE REFRACTION-CHANGES DEPENDENT UPON GLYCOSURIA.*

BY GEORGE M. GOULD, M.D.,

PHILADELPHIA.

THE majority of oculists have long but vaguely known that glycosuria produces changes in the refraction of the healthy eye, but no one seems to have gathered the facts to a focus or gleaned the lessons derivable from their study. When a perfect illustration of the condition came into my practice I was therefore astonished to find that the few reports of cases observed in the past were mostly badly reported, a portion probably incorrectly reported, and a series of eight absolutely irreconcilable with another series of eight. Moreover, the theories as to the mechanism of the refraction-changes were as numerous as vague, and as irreconcilable as the reports of the cases themselves. As I tried harder and harder, in my first studies of these cases and theories, to understand them and resolve the mysteries, I found myself always deeper in doubt and amazement. But when I faced a final charting of the cases, the problem seemed to me to be suddenly resolved. The report of my case is as follows:

Gould's Case.† Dr. M., a busy physician carrying on a large practice, had for many years been a patient of mine, and by frequently repeated examinations I had kept close watch of his refraction-errors, because the least eyestrain in so severe a worker and student meant a vast deal for him. I may add that this patient also took a great deal of personal interest in the eyestrain problem, and had learned by bitter experience, subjective and objective, that certain theories as to the ocular origin of much systemic disease were true. He was, therefore, admirably fitted to help me correlate the facts to be described. Another condition to be noted is that the patient is now 58 years of age and myopic, so that the chance of error from incorrectly diagnosticated accommodation is quite out of the count.

In December, 1902, Dr. M. had been wearing

R. −Sph. 2.62 −Cyl. 0.75 ax. 35° = 20/20+
L. −Sph. 2.62 −Cyl 1.25 ax. 167° = 20/20+
B. E. −Sph. 0.87 and Cyls. for near work, in bifocals.

This error of refraction, although frequently tested had not materially changed for many years. On the 18th of the month my patient appeared with clearly marked symptoms of eyestrain. I found a sudden increase of myopia, measured by

R. −Sph 3.25 −Cyl. 0.75 ax. 25° = 20/20+
L. −Sph. 3.25 −Cyl. 1.50 ax. 166° = 20/20+
B. E. −Sph. 1.12 and cylinders for near.

There was also a noteworthy limitation of the range of accommodation. This increase of myopia in a man of 53, in one apparently healthy, although explainable, perhaps, in other ways, aroused my suspicions. Rigid questioning brought out the confession of several symptoms, which made me urge careful urine analysis. Quickly came the answer: "The urine is loaded with sugar."

The strictest dieting was immediately carried out, and within a few days every trace of sugar was eliminated from the urine. But then, as promptly, there was again eyestrain. A reexamination of the refraction showed that the errors had returned almost exactly to the point of seven days before.

In the next four years the total of the myopic corrections increased slowly and more in the last year, when Dr. M.'s health began to show some instability. I warned in vain. The sequel proved that he had simply grown more careless as to his food, eating sweets and starches with thoughtless indifference. In December, 1906, the errors were demonstrated to be

R. −Sph. 2.87 −Cyl. 0.87 ax. 25° = 20/20+
L. −Sph. 3.00 −Cyl. 1.50 ax. 172° = 20/20+
B. E −Sph. 0.50 and cylinders for near.

By February 18, 1907, symptoms of ill-health began to grow manifest, even to the careless-of-self mind of the patient, and he resumed the long-neglected analyses of the urine. The first one showed again an extremely high percentage of sugar. He was also having eyestrain, ignored for the time being, in his interest in other things. Of course the rigid diet was again put into force, and in two or three days not a sign of glycosuria could be detected. Then the patient returned to me with greater eyestrain than ever, and again there was the astonishing reduction in myopia measured by

R. −Sph. 2.00 −Cyl. 0.62 ax. 20° = 20/20 + } Distance
L. −Sph. 1.87 −Cyl. 1.37 ax. 170° = 20/20+ }
R. Cyl. alone } Near
L. +Sph. 0.12 and cylinder }

These corrections brought perfect visual acuity for distance and near, absence of all eyestrain, and the ocular conditions, with unessential changes, will probably remain the same so long as there is no glycosuria.

Grimsdale's Case,[1] of a woman aged 45, who came October 7, 1897, wearing for some years, for near vision,

R. +Sph. 1.00 +Cyl. 0.75 ax. 160°
L. +Sph. 1.75

Fourteen days previously the woman had noticed that her refraction had suddenly changed, so that her reading glasses were no longer needed, and distant objects were not seen so clearly as formerly. Vision, natural, was 6/60 in each eye. Without mydriasis the errors were estimated as follows:

R. −Sph. 2.00 −Cyl. 0.50 ax. 180° = 20/20
L. −Sph. 2.00 = 20/20

With this correction the patient at once said, "That is how I used to see." No mydriatic was used, nor was the range of accommodation tested. The right lens had scattered central opacities, the left was clear. At this time there were 26 grains to the ounce of sugar in the urine. Treatment was now instituted, and in ten days the report of the oculist was

R 6/18 −0.5 = 6/12, not improved by cylinder
L. 6/6 No Hm.

*Read before the Ophthalmic Section of the College of Physicians, Philadelphia, April 16, 1907.

†Hitherto unpublished report.

"She now required + Sph. 2.50 to enable her to read 0.3 Sn. at one foot." "She was on strict diet, and the total amount of sugar had much diminished." "The right lens presented considerable irregular astigmatism." In a few weeks death occurred following diabetic coma.

De Schweinitz's Second Case was that of a girl 20 years old, with no organic lesions except congenital posterior capsular opacity in each eye. Under cycloplegia the errors were determined

R. + Sph. 0.25 − Cyl. 0.75 ax. 135° = 6/10
L. − Cyl. 0.62 ax. 15° = 6/7 ½

Six months later the patient returned, complaining of rapidly deteriorating vision following some prolonged illness. It was learned that diabetic symptoms came on shortly after the first visit, and that large quantities of sugar had continued in the urine ever since, despite treatment. No mydriatic was now used, one judges, but a myopia of 3.00 D. in the right eye, and 2.00 D. in the left was demonstrated, with vision of 6/22 and 6/12 respectively. Systemic treatment was continued, and in three months the visual acuteness was holding its own. But edematous choroid and vitreous opacities had now become manifest. In another month the myopia of the right remained the same, but that of the left eye had become 5. The patient died not long after this. Dr. de Schweinitz concludes that a diffuse edematous affection of the choroid is the underlying pathological process in such cases.

Appenzeller's Case (Graefe-Saemisch) was of a patient 43 years old, who had 1.00 D. myopia while the glycosuria existed, but when under treatment the urine was normal emmetropia again returned.

Hirschberg's Case.[2]—Hirschberg gives a brief résumé of the case of a man 48 years old, who had for many years seen plainly with — Sph. 9", *i.e.* — Sph. 4.62 D., but who now complained of dimness of vision. With his old lenses he could not read any longer. There was no paralysis of the accommodation. The proper correcting lenses were now found to be — 8" Sph., — Cyl. 40" ax. 180°. Diabetes had been present for 14 days, followed by some (doubtful) loss of weight. The eye-grounds were normal. The urine contained 6¼ per cent. of sugar.

Dujardin's Case[3] was of a woman 69 years of age, applying April, 1899. There was high glycosuria, and despite treatment the percentage of sugar remained between 70 and 80 grams per liter. The media were clear and the eyes healthy. She could no longer see well at a distance, although formerly she had had sharp acuteness. For reading she had required + Sph. 4. D., but could not now read with these lenses. The pupils would not widen under atropin. By retinoscopy about 5. D. of myopia was made out. Homatropin was ordered as a collyrium and belladonna given internally on the theory that a spasmodic condition of the ciliary muscle existed. A month later conditions remained the same.

Risley's First Case.[4]—A woman of 49, having had glycosuria in the past, complained that, with the suppression of the glycosuria, and consequent improvement in general health, her vision had grown rapidly worse. She was wearing + Sph. 2.75. The dimmed vision had been observed only within a few days. Under mydriasis the errors were

R. + Sph. 5.00 + Cyl. 1.25 ax. 75° = 20/20
L. + Sph. 6.00 + Cyl. 0.75 ax. 105° = 20/20

In ten days glycosuria returned, and with it dimness of vision again, and the correction (nonmydriatic, one gathers) was

R. + Sph 3.00 + Cyl. 1.25 ax. 75° = 20/20
L. + Sph 3.50 + Cyl. 0.75 ax. 105° = 20/20

Fifteen days after this she chose (nonmydriatic, probably)

R. + Sph. 1.25 + Cyl. 1.25 ax. 75° = 20/20
L. + Sph 1.50 + Cyl. 0.75 ax. 105° = 20/20

Risley's Second Case.[4]—A man, 74, suffering from saccharin diabetes for at least six years, was the subject. In August, 1896, the errors were

R. + Sph. 1.50 + Cyl. 1.25 ax. 180° = 6/7 1/2
L. + Sph. 1.25 + Cyl. 1.25 ax. 180° = 6/10

The lenses were cataractous. In April, 1897, the vision in each eye remained the same, presumably, with the same errors of refraction. Fourteen days later dimness of vision was complained of, and the visual acuteness with his distance-glasses was with each eye 6/30. No sugar, or but a trace, was present, and the man now selected

R. + Sph. 2.50 + Cyl. 1.25 ax. 180° = 6/7 1/2
L. + Sph. 2.00 + Cyl. 1.25 ax. 180° = 6/10

Within three days of a month later the patient had been compelled to return to his old glasses within a few days, and he now chose this correction, the first above given, with almost the same visual acuteness. Sugar was again found—4.20 per cent., and a specific gravity of the urine of 1,027.

*Carpenter's Case** was of a woman, 51 years old; consultation was for dimness in reading during last six months. There was no local ocular disease. Refraction (without a mydriatic) was diagnosed

R. − Sph. 0.25 − Cyl. 0.50 ax. 90° = 20/20
L. − Cyl. 0.50 ax. 90° = 20/20
+ Sph. 1.75 added for reading. Reading glasses only ordered.

Six years later the patient returned, stating that her reading glasses had proved comfortable until within a few weeks. Her correction was now found to be

R + Sph. 1.50 = 20/20 } Distance
L + Sph. 2.50 = 20/20 } Distance
With + Sph. 2.25 added for reading } Bifocals ordered.

Four weeks before this last visit glycosuria had been diagnosed by her physician, and treatment begun, with great decrease of the percentage of sugar. Still no local disease of the eyes was found. In three weeks she returned to her original careless diet (rich food, sugar, etc.), and convex lenses made vision worse, but R. — Sph. 0.75, L. — Sph. 0.50 again brought the distant acuteness to normal.

De Schweinitz's First Case[5] was of a patient, a man of 47. The man had fairly healthy eyes, but the report does not state whether the first refraction was made under cycloplegia, or not. "Each eye was hyperopic, + 1.25 D. The complaint was of failing vision in presbyopia. One gathers that glasses were ordered for presbyopia only. Four years later the complaint was of dimness of vision for distance, "scarcely one-half" what it had been four years previously, *i.e.* normal, and — Sph. 0.50 was now required to give normal acuteness. Glycosuria was suspected and demonstrated. By June 14, 1895 (a month later) sugar had been extinguished. Although the static refraction does not seem to have been determined—a matter of regret—the inference is that the change of refraction from + Sph. 1.25 to — Sph. 0.50 was due to the glycosuria. As there was no decided lesion to be discovered by the ophthalmoscope, etc., the inference seems justified, and another case of displacement of the focus forward is to be added to the list.

Neuberger's First Case.[6]—A 50-year-old woman who had been emmetropic and able to read the finest print with + Sph. 2.00, came four months later, reduced in flesh and with a myopia of R. 1.5 D., L. 2.00 D. Smallest print could now be read with + Sph. 1.5 D, and L. + 1.00 D. Weakness of the accommodation was also present. The lenses were,

*Not published. MS. report kindly loaned by Dr. Carpenter of Philadelphia.

and remained clear. The urine contained 3.5 per cent. of sugar. In about three weeks emmetropia returned and + Sph. 2.5 D. was required to read fine print. The myopia had thus disappeared, *although at this time the glycosuria had increased to 7 per cent.* Diabetic retinitis later appeared, but the lenses continued clear and the refraction emmetropic.

Neuberger's Second Case[6] was of a woman of 48, who two years before had a hyperopia of 0.75 (+ 1.5 for near), but now was myopic, R. 1., L. 2.5 D., and no glass for reading. The lenses were clear at first, but later became obscure. Six months later the myopia was R. 3.00, L. 8.00 D., with cataract progressing.

Alexander's Case.[7]—The patient was a man of 57 years of age, who had felt a decrease of visual acuteness for distance during the last 14 days. A myopia of 1.00 was diagnosed. For near + Sph. 0.75 was sufficient when 1.75 was before demanded. The sugar was 5.7 per cent. In 8 days dieting brought the urine to normality, emmetropia returned, but this in 5 days changed to a hyperopia of 1.75 D., the urine continuing free from sugar. In epitomizing this history Groenouw* rightly says the original refraction was probably hyperopia, which later became manifest.

*Groenouw's Case.**[8]—A woman of 55, suffering from diabetes, suddenly acquired a myopia of 1. D., which in 3 weeks became emmetropia. The lenses were clear. This is given by Groenouw as a case of latent hyperopia becoming manifest.

Doyne's Case† was of a physician of 40 who consulted the oculist for failing sight. The man was suffering from acute diabetes. Three diopters of hyperopia were found, and this correction was ordered and the glasses were worn without discomfort. Practice was discontinued and a sea voyage undertaken, but upon his return he complained of dimness of vision for distance. The hyperopia had lessened and + Sph. 2.50 each eye again gave normal vision. Soon afterwards dimness of distant objects again recurred and the strength of the glasses had again to be reduced, "and later on, when the sugar disappeared, under homatropin freely used, only 0.75 of hypermetropia existed."

Horner's Case[9] was of a woman of 55. The hyperopia had rapidly increased; it was 1/14" at the time of the visit, but with improvement in the general health it sank to 1/48".

Cohn's Case (Graefe-Saemisch) was one of increase of the hyperopia in a 68-year-old woman, from 1.50 to 3.00 D.

Landolt's Case.[10]—"We have observed, among others, a most interesting case of this kind. A lady had a fall and became diabetic as a consequence of this traumatism, although her general condition was not much affected by it. At the same time she commenced to no longer see well at a distance, and found the spectacles, that she had previously worn on account of her presbyopia, to be insufficient. The refraction could be determined, in this case, with the utmost accuracy, not only because the patient was very intelligent, but because she had reached an age at which the accommodation is almost *nil*. I made out a hyperopia of 0.5 D., which certainly had not previously existed. It increased and then diminished, according to the amount of sugar excreted, and finally disappeared entirely. So that, when this traumatic diabetes was cured, the patient could dispense with her distance-spectacles, and substitute, when reading, her former spectacles for the stronger glasses which she had been obliged to resort to. I have seen the patient for several years, and it has been extremely interesting to note that each little recurrence of diabetes has announced itself at once by a diminution of refraction, to such a point that the curve of hyperopia was, so to say, parallel with that of the quantity of sugar eliminated with the urine."

Gallus' Case.[11]—A man aged 51, under treatment for diabetes for two weeks, noticed impairment of vision for distance. Sph. + 2.00 for reading had become too weak, although he "could see well through them into distance." Examination revealed R. + Sph. 1.50 + Cyl. 0.50 ax. 180° = (What?) L. + Sph. 2.00 + Cyl. 0.50 ax. 180° = (What?) With + 2. added he could read the smallest type. Under treatment glycosuria ceased, and in two months the hyperopia had subsided so that the patient needed only cylinders and could read again with + Sph. 2.00 + Cy. 0.50.

Lichtenstein's Case[12] occurred in a man seventeen years old. The refraction is given as + Sph. 1.50, estimated without a mydriatic, but 12. D. + Sph. lenses were required to enable the patient to read from print at 9 cm. The paralysis of the accommodation is said to have been "complete." He had suffered from no diseases (except glycosuria) which would cause this paralysis. Despite treatment his glycosuria had increased in severity, and urinalysis now showed 4.5 per cent. of sugar present, and some six liters of urine were voided daily. The patient was sent to a colleague, and the next day the hyperopia was found to be 2.5 D., with 13 D. lenses required for near. Homatropin now showed the same 2.5 D. of hyperopia. Five days later it was 3.5 D., demonstrated by atropinization and skiascopy. For 14 days the conditions remained the same, but the young man felt better. Now 3.5 D. was required for distance, but only 11 D. for near. But this was soon reduced to 6 D., and in about two weeks from the first visit it had fallen to 5 D. The hyperopia gradually fell from 3 D. to 2.5 D., then to 2 D., and finally to 1.5 D., the point whence it started on March 8, 1906. Lichtenstein says the doubt as to the latency of hyperopia was excluded by his atropinization. L. explains that in this case two factors united to produce the result, paralysis of the accommodation, and transitory hyperopia. He explains this as due to loss of water by the contents of the globe and a resultant shortening of the anteroposterior axis.

Sourdille's Case.—In an emmetropic woman, 53 years old, S. observed a hyperopia of 2.00 D. occur, which again disappeared with the disappearance of sugar.

Lundsgaard's Case.[13]—The patient was a woman, who in 1892 was found to have + Sph. 0.50; "the ophthalmoscope showed emmetropia." In the summer of 1905 there was great thirst and polyuria, but according to the general physician no sugar or albumin existed in the urine. In 1906 traces of sugar appeared, and in a month the percentage was 7¾. Dieting reduced the sugar somewhat, but sudden dimness of vision called attention to the eyes when a hyperopia of 2.50 and 2.00 was found. The media were clear. Accommodation accorded with the age. The percentage of sugar was now reduced but not extinguished, and the hyperopia fell; finally the sugar was eliminated entirely and on the 19th of November, 1906, the hyperopia returned to the figure of 1902.

These twenty-two cases are not all those which, by more rigid search or less rigid rules of exclu-

*Reported in the discussion of Mr. Grimsdale's case.[1]

†Augenleiden bei Diabetes Mellitus, Groenouw, 1907, p. 46.

sion, might possibly be included as data.* If we arrange them in three series we find the first, composed of those in which myopia is increased by glycosuria (or decreased by its extinction) is made up of six—those of Gould, Grimsdale, de Schweinitz's Second, Appenzeller, Hirschberg, Dujardin.

The second series, those in which hyperopia is decreased by glycosuria (or increased by a return to normality) is made up of eight—those of Risley's Two, Carpenter, de Schweinitz's First, Neuberger's Two, Alexander, and Groenouw.

The third series, those in which hyperopia is reported as increased by glycosuria, is composed of eight—Doyne, Horner, Cohn, Landolt, Gallus, Lichtenstein, Sourdille, Lundsgaard.

Principles Governing the Determination of the Refractive Conditions.—It is of first importance that in the report of a case the precedent static refraction must be the basis of any comparison. In all persons under 60 years of age, except occasionally in myopia, the accommodation, unless paralyzed, would make a possible error rendering all comparisons inaccurate, and if under 50 years almost wholly untrustworthy. The reports of glycosuric refraction change in hyperopes under 50, unless the diagnostic tests have each been made under cycloplegia, are of little value, except that the physician believed and reported his belief that the presence or absence of sugar in a general way indicated certain refraction changes. If the presbyope is highly myopic that gives an added element of accuracy. Still greater precision is to be predicated in cases in which previous accurate refractions have been made frequently and over a long period of years. The astigmatic error, once correctly determined, may be discarded in speaking subsequently of the cases because this changes but slightly in cases of paralyzed accommodation, so that the statement of the relative myopia and hyperopia is practically all that is necessary. In no case so far reported has there been any exact mathematical relationship stated between the varying amounts of the sugar and the degrees of the resultant refraction-change. This valuable aid must therefore be left out of the count. In the reports of future cases it should be made out and reported upon. The absence of local ocular disease that would obscure the nature of the refraction changes must also be insured. When glycosuria has set up extensive choroidoretinitis, pronounced cataract, etc., a new factor is added which may be the cause of so much doubt that the report is made suspicious. The tests, to be of the best value, must be in cases with acute glycosuria, in which the eyes are so far healthy, the media sufficiently clear, the funduses so nearly normal, the acuteness of vision so good, etc., that the measure of refraction is not in doubt. The shorter the period of time between the tests of the glycosuric and the nonglycosuric refraction the more valuable will be the data obtained, and the more convincing the deductions made from them. Lastly, the oculist must be a refractionist, believing in the value of accurate refraction tests, habituated to make them, and seriously aware of the evil results of bad and slipshod refraction to eye and general system. There is little or no possibility of securing a trustworthy estimate of the refraction in all Europe, where the refraction is pronounced alike in both eyes, astigmatism ignored, etc., and whenever a report comes to us wherein the refraction has been estimated with the ophthalmoscope, and bearing ludicrous internal evidences of bungling, and contradicting the reports of careful and keen-witted refractionists, there may be no delay in speedily setting it aside as worthless, or of little scientific value.

Exclusion of reports according to the foregoing principles becomes easier when we notice that there is no reported case of myopia in which glycosuria has not had the effect of increasing the myopia—that is, of bringing the focus of the dioptric system forward. All such cases are logical, one may say, as naturally the effect of glycosuria must be to affect the focus in that way. Whatever be the mechanism intermediating the change it is impossible to comprehend how glycosuria can displace the focus posteriorly. Now, as the myopia of an eye is far more easily and accurately measured than the hyperopia, and without a cycloplegic, it is not surprising that all observers, good or bad, unite, in their reports, that glycosuria, if it changes the refraction at all, increases the preexisting myopia.

Confirming this result we find that the reports of eight cases of change in hyperopia also say that the effect of glycosuria is to advance the focus exactly as happens in myopia. And in this series occur the names of such trustworthy refractionists as Risley, Carpenter, de Schweinitz, etc.

It is simply inconceivable that the mere accidents of the location of the retina in the path of the refracted cone of light-rays should have the reverse effect in displacing the focus in hyperopia, from what it does in myopia. Therefore when eight reporters find such an illogical if not impossible reversal of the natural consequences as testified to by fourteen, it behooves us to doubt the accuracy of the oculists' tests and reports rather than to indulge a belief in the inherently improbable and impossible. Let us briefly glance at the cases critically of those reporting increase of hyperopia:

In Doyle's case, the patient was 40, no mydriatic was used at first and as the only true basis of comparison, and the squint of the corner of the mouth becomes visible when it is said that three diopters of hyperopia were found! The case was pretty plainly one of latent hyperopia, astigmatism, etc., becoming manifest "later on," because of the frequent effect of glycosuria on the accommodation, or because of advancing presbyopia. It should therefore be set aside. No wonder that Mr. Doyle had no explanation to offer.

Graefe and Saemisch explain Horner's case and that of Cohn as due to latent hyperopia. Schmidt-Rimpler, and Groenouw also explain similar cases in this way.

In Landolt's case there is too much vagueness in the report and too little increase of the hyperopia—only 0.50 D.—to make us heed the claim of "utmost accuracy," made in behalf of the improbable.

The patient of Gallus was 51, the acuteness of vision was not noted, no mydriatic was used, etc. The change was probably in the accommodation, not in the (untested) static refraction.

Of Lichtenstein's case one doesn't know what to say, except that the inherent absurdity of 2.5 D. hyperopia with 13. D. required for near vision is so great as to make us smile with incredulity. Then it must not be forgotten that atropin in Dujardin's case did not even widen the pupil. Until competent refractionists report other cases similar to this one it must remain as a single and anomalous empiric fact in which other factors than glycosuria were present. This is the only case reported of one so young as 17 years, a fact to be remembered.

Sourdille's case was in a patient 53 years of age, and no mydriatic was used. *Exit!*

In Lundsgaard's case, "the ophthalmoscope

*Kako's case of developing + astigmatism, *e.g.* is omitted for evident reasons.

showed emmetropia," and with that admission "the defence may rest its case." (In speaking of his own case Schmidt-Rimpler (*Die Erkrankungen des Auges, etc.*, Wien, 1905), says, "the upright image demonstrated a hyperopia of 0.5 D.," so that case may also go to the Jury forthwith.)

We may therefore feel no compunctions in excluding on the ground of erroneous diagnosis due to failure to estimate correctly the static refraction almost all of the cases so far reported in which it is claimed that glycosuria removes the focus of the dioptric system to a position posterior to that occupied in the previous nonglycosuric period.

It would require an entire paper and a long one, to enumerate and critically judge of the theories advanced to explain the modus operandi of the effect of glycosuria upon the refraction. I doubt if the most capable mind could do much toward clarifying the obscure subject. I had made a list of these numerous theories, but I do not think it would be edifying to read it. The arguments point toward a consensus of opinion favoring increased density of the ocular fluids, functional disturbances and paralysis of the lens and ciliary muscle, etc., rather than to changes in the corneal curves, changes in volume of the contents of the globe, or displacement of the macular region of the retina.

As to the significance of the phenomenon, everybody has emphasized the importance of the recognition of the refraction and accommodation changes as warnings of the existence of the systemic disease. In the days of life insurance examinations, of routine urinalyses by the general practitioner in almost all cases of ill-health, of the striking evidences to the patient of thirst, polyuria, etc., the warnings seem somewhat antiquarian, at least not of the first importance. The wideawake American oculist would prefer to doubly emphasize the overlooked truths: (1) That the eyestrain preceding the glycosuric refraction-change may have been a prime factor in producing the functional dietetic and nutritional disease called glycosuria; most significant is the fact that the great majority of the cases occur during the presbyopic period; (2) that the secondary refraction-change serves as a perfect illustration of the increase of the diseases due to overstrain by the proverbial vicious circle, increasing the irritation and nutritional abnormalism by the secondarily induced refractional changes caused by the glycosuria: (3) the necessity of preventing quick-following ocular disease, both functional and organic, by heeding the accurate warnings given by the refraction changes consequent upon early and curable glycosuria. But whatever the point of view, and whatever the injuries done or threatened, the accurate diagnosis of the static refraction overtops and conditions every measure of prevention and every step of progress either in science or in therapeutics.

SOME UNUSUAL RESULTS OF INTRATHORACIC COMPRESSION.

By THEODORE B. BARRINGER, Jr., M.D.,

NEW YORK.

INSTRUCTOR IN MEDICINE, CORNELL UNIVERSITY MEDICAL COLLEGE.

Collateral venous circulations of unusual extent, following compression and thrombosis of the superior vena cava and of the left innominate vein respectively, and an uncommon physical sign of bronchial compression, are the points of interest about the three cases here reported.

Case I.—The first case is one of gradual narrowing and obliteration of the superior vena cava by probably a mass of sclerosed and caseous bronchial glands.

The patient, male, white, sixty-two years old, a watchman, of Irish nativity, was first seen in March, 1906. He had had measles, whooping cough, and gonorrhea. About twenty years ago he had noticed a swelling of the superficial abdominal veins. The onset was apparently gradual, and there was no history of thrombosis or phlebitis of the veins of the face, neck, or arms. Since July, 1905, he had suffered from cough, mucopurulent expectoration, hoarseness, and loss of weight.

He was an emaciated old man, pallid and dyspneic. All of his superficial arteries were sclerosed. There were slight varicosities of the veins of both legs. The anterior portion of the chest, the front and sides of the abdomen, and the left lumbar region showed extraordinarily large and tortuous veins, of which the superior and inferior epigastric were the most prominent. The blood current in these veins was downward. His lungs showed consolidation of the upper right lobe and infiltration of the remainder of that lung and of the upper left lobe. The heart was slightly enlarged, intermitted occasionally, and showed an accentuated aortic second sound and no murmurs. His sputum contained numerous tubercle bacilli.

The fluoroscope showed, in addition to the lung lesions, a shadow about 4 c.c. in diameter, just at the right of the heart shadow, and a chain of enlarged bronchial glands at the left. The shadow did not pulsate and was taken to be a mass of sclerosed bronchial glands. The enlargement of the abdominal veins is shown in the illustration.

The size of the veins involved in the collateral circulation and the downward current of blood therein, led us to make a diagnosis of obstruction in the superior vena cava. This history of a slow onset, and the absence of any history of sudden edema and cyanosis of the arms or face, enabled us to exclude a thrombosis of the cervical or arm veins, which sometimes precedes a thrombosis of the cava superior, and made probable a gradually increasing compression as the cause of the obstruction. This cause would permit the gradual and uneventful establishment of a collateral circulation which ensued in our case. The identification by the fluoroscope of what was probably a mass of sclerosed and caseous glands just to the right of the heart, at the site of the superior cava, revealed the compressing factor.

Osler has reported three cases of obliteration of the superior vena cava,[1] together with a very com-

plete summary of cases found in the literature up to 1903. Eppinger[2] reports a case in which the autopsy showed the superior cava changed into a thick fibrous cord, surrounded by degenerated bronchial glands. Schrotter[3] also reports a case of marked narrowing of this vein by a group of sclerosed and caseous bronchial glands in a tuberculous patient.

In cases of complete closure of the superior cava, the blood regurgitates from the obstruction, through the cava to the innominate vein, to the internal mammary, to the superior epigastric, to the superficial and the deep epigastric, to the iliac veins, and so to the inferior cava and the heart. Many other collateral circulations may be brought into play, depending somewhat on the site of the obstruction—whether above or below the opening of the azygos vein into the superior cava. If below, the blood passes from the superior cava through the azygos vein, to the lumbar and renal veins and thence to the inferior cava. The enlargement of one of the

left lumbar veins in our case showed that the vena azygos was concerned in the collateral circulation and that therefore the obstruction was below the opening of that vein.

Rapid closure of a vein is attended by marked vascular disturbances, as edema, cyanosis, etc., and only after a period of time are these overcome by the formation of a collateral circulation. The gradual closure of the vein in our case prevented the appearance of any sudden circulatory incompetence.

Case II.—The second case exemplifies the effect of sudden venous obstruction. The patient was a mattress maker, thirty-three years old, who had never had any serious illness. He denied syphilis, but had always been a heavy drinker. On February 16, 1906, immediately after a paroxysm of coughing, he felt a "snap" near the left "collar bone." That afternoon the left shoulder felt sore, and the soreness gradually extended down to the left arm and left side of the chest. The next day he noticed swelling of the left side of the neck just above the clavicle, of the left side of the chest around the nipple, and of the left arm and forearm. The swelling and soreness have gradually increased. The pain is now (four days after the onset) most marked over the upper inner portion of the left arm.

The patient is an obese plethoric man, who is slightly dyspneic. The left side of the neck just above the clavicle is distinctly swollen and cyanosed. The upper left chest as far as the nipple, and the left shoulder, arm, and forearm are also swollen and cyanosed. The swelling does not pit on pressure. There are numerous small dilated veins on the left chest and shoulder. There are redness and tenderness along the lower portion of the left axillary vein. There is decided dullness over the manubrium and in the second left intercostal space next to the sternum. There is slight dullness over the upper left chest as far as the third rib in front and the spine of the scapula behind, and over this area the tactile fremitus, breath, and voice sounds are decreased; also over the left supraspinous fossa the expiration is distantly bronchial—all of which are evidences of compression of the left bronchus. The heart is negative. The left radial pulse is slightly smaller than the right. There is slight trachial tugging. The movements of the vocal cords are normal.

The fluoroscope shows a small pulsating shadow above the heart to the left of the sternum, and a diagnosis was made of aneurysm of the transverse arch compressing the left brochus and the left innominate vein.

The edema and cyanosis disappeared a few weeks later. Ten months later the small veins on the chest and shoulder observed during the first visit showed a marked increase in size and number. The blood current in these large veins was downward. The fluoroscope showed that the aneurysm had increased markedly in size, the shadow extending almost 8 cm. to the right of the sternum. There were no evidences of bronchial compression.

In this case the aneurysm first produced a narrowing, but no complete obstruction of the left innominate vein. Following this narrowing numerous small varicose veins developed on the chest and shoulder and were observed at the time of his first visit. These may be regarded as evidence of the beginning collateral circulation, and had probably been present a long time. Then a thrombosis of the innominate vein suddenly supervened, as was evidenced by the sudden venous congestion of the arm, chest, and neck. That the thrombosis completely closed the vein is shown by the present extensive collateral circulation.

The non-pitting character of the edema in these cases is to be explained by a greater involvement of the subfascicular rather than the subcuticular veins.

The compression of the left bronchus showed the usual physical signs of bronchial stenosis and will be contrasted with some unusual signs of this condition observed in our third case.

Case III.—This patient was a driver, twenty-nine years old, of American birth. His family history was negative and he had had no infectious diseases. When seventeen years old he had had a chancre, but no secondary symptoms. He had smoked and used whiskey to excess for years. In August, 1905, he began to suffer from a "croupy cough," with scanty expectoration, and at times slight pain under the sternum. He also had noticed some shortness of breath on exertion and some cardiac palpitation, which have continued. On November 15, 1905, his physical examination was as follows: A well-nourished, muscular young man, somewhat dyspneic, with a frequent, harsh, brassy cough. His heart was of normal size, with rapid and regular action,

and showed no murmurs. His pulse was 132 to the minute, regular, of fair tension, and corresponded in the two radials. The respirations were 32 per minute, and the lungs, of normal size, showed everywhere many sibilant râles.

On November 22, 1905, the patient was seen again. He was dyspneic, and examination of the lungs showed a remarkable condition. The left lung moved very slightly with respiration, transmitted a very feeble fremitus over the upper lobe, gave a markedly hyperresonant note, and was much increased in size, entirely obscuring the heart dullness. Breathing over the left apex, anterior, was heard *only* during the latter half of inspiration and then it sounded as if air were rushing through a narrowed bronchus. Posteriorly the breath and voice sounds were almost absent. There was no tracheal tugging. The larynx was not examined.

Excepting the peculiar character of inspiration over the left apex in front, the physical signs were those of marked emphysema of the left lung. While we suspected an aneurysm pressing on the left bronchus, these physical signs were most puzzling.

He was sent up to the hospital ward where he died ten days later from profuse hemoptysis, losing about a liter of bright red blood. Shortly after admission the peculiar physical signs over the left lung disappeared and evidences were found of an aneurysm of the transverse arch presenting at and to the right of the manubrium sterni. Unfortunately, no radiograph was taken, nor was an autopsy secured. The diagnosis was made of an aneurysm of the transverse arch which had compressed the left bronchus and trachea, producing the dyspnea and unusual physical signs.

The signs of compression of a bronchus, as given in the half-dozen books on diagnosis we have consulted, are dullness, feeble or absent tactile fremitus, and diminished or absent breath and voice sounds over the corresponding portion of lung. These signs were present in the preceding case, but this case showed a hyperresonant note and a marked increase in size of the lung, so we were obliged to conclude that other conditions than those ordinarily found in bronchial stenosis must have been present.

A hyperresonant or tympanitic note over an organ can be caused by an increase in the air content of the organ or by a relaxation of the enclosing walls, which latter produces a decrease in the tension of the contained air.[4] Relaxation of the alveolar walls as a result of the absorption of air from the lung tissue corresponding to a stenosed bronchus, might be evinced by a hyperresonant note, but in our case the lung was decidedly increased in size, so, following the above law, the air content of the affected lung must have been increased.

The explanation given by Hoffman[5] of the anatomical conditions in cases of bronchial stenosis seems very rational and explains why there is an increase in the air content of the corresponding lung, producing a localized emphysema. He says: "The *gradual narrowing* of a bronchus favors accumulation of air and increased pressure in the peripheral section of the corresponding lung, and as long as the condition remains comparatively aseptic, emphysema is the chief result. *Sudden closure* of a bronchus results in atelectasis, and if there is no infection, atrophy and cirrhosis of the corresponding lung tissue. In a gradual narrowing, the air, during inspiration, is sucked through the stenosed place, but the expiratory power is not sufficient to expel it, for the driving power during expiration is only the elasticity of the lung tissue lying below the stenosis. The great expiratory pressure, produced by the muscles of expiration, has, in this case, but little effect, for it can never act so uniformly from all sides, as does the elastic tug which draws air into the bronchus—it acts spasmodically and presses equally on all parts of the thorax. Also, any tough mucus present may act like a valve, permitting the air to enter easier than to escape."

The condition obtaining in bronchial asthma affords another illustration of Hoffman's explanation. Here we have a stenosis of the smaller bronchi due either to spasm or to turgescence of the mucous membrane, and very frequently an extensive emphysema.

Irvine[6] concludes as a result of his clinical and post-mortem experience that (1) emphysema follows compression of a bronchus; (2) bronchiectasis may be associated with this emphysema; (3) destructive pneumonia may further ensue; (4) collapse of the lung may occur early in the stage of compression. He reports four cases of aneurysmal compression of the left bronchus, and in but one of these were the physical signs suggestive of emphysema of the left lung. Autopsy showed that in two of these cases the left lung was enlarged and the seat of various infective processes, that in one case the left lung was partially collapsed and partially emphysematous, and that in one case the left lung was normal in size. The right lung in all of the four cases showed a compensatory emphysema.

One would judge from the statements of these authors that pulmonary emphysema, following bronchial stenosis, is a very frequent occurrence, and yet none of the leading English authorities on physical diagnosis mention it. The percussion note is uniformly described as normal or dull, but no reference is made to increase in size of the lung.

The probable explanation for this is that the conditions for rapid development of emphysema, namely that degree of stenosis which will permit of free ingress and but little egress of air, or the presence of a viscid, valve-acting secretion immediately below the stenosis, are rarely present. The emphysema generally develops slowly, and the concomitant infectious processes obscure the emphysematous signs. Nevertheless it should be borne in mind that localized pulmonary emphysema, although rarely seen, points to a bronchial stenosis.

These three cases were seen in the Second Medical Division of the Bellevue Hospital, Out-patient Department, and it is through the courtesy of Dr. N. R. Norton, Chief of the Dispensary, that I am enabled to report them.

The Bier Treatment.—Too prolonged or too rapid and vigorous use of the pump in the Bier apparatus will frequently cause a rupture of the superficial blood-vessels, and in many cases severe sloughing of the superficial parts ensues, the result of the treatment being worse than the primary cause of the trouble. Application of the Bier cup to an abscess for four to five minutes twice a day is more beneficial than a single ten-minute application.—*American Journal of Surgery.*

DERMATOLOGICAL TRANSITIONS.

By OMAR M. WILSON, M.D., C.M.,

OTTAWA, ONTARIO.

LATE HOUSE PHYSICIAN, NEW YORK SKIN AND CANCER HOSPITAL.

In the practice of medicine to-day, we are often prone to be too specific in our diagnoses, too apt sometimes to overlook the fact that there may be a gradual evolution of one process or disease into another—in short, a transition. In no branch of medicine probably, do we find these changes occurring so frequently, and with such marked emphasis, as in dermatology. Broadly speaking, there are two types of transitions encountered in the practice of cutaneous medicine: (1) The transitions of diseases; (2) the transitions of lesions. The former has two main subdivisions: False and True.

False Transitions.—Under false transitions we class certain conditions in which a new lesion or a new chain of symptoms has been added to or grafted upon a preexisting disease or lesion. Cases are reported from time to time where, for example, epithelioma has developed upon the site of an old chancre or gumma; lupus vulgaris has been followed by epithelioma; lupus erythematosus has assumed an epitheliomatous tendency in its later stages,* while cases of scabies, terminating in eczema, and initial lesion supervening upon herpes preputialis are of everyday occurrence.

Transitions due to Traumatism.—Many hold that most of these changes are to be classed in the category of "cause and effect." The pruritus of scabies, relieved by constant scratching, changes into eczema, in patients predisposed to this disease—the inflamed, thickened, weeping condition being due to the mechanical irritation.

Chronic eczema of the palms often changes into keratosis palmaris from a similar cause. The small warty papule, picked, scratched, or otherwise irritated, becomes epitheliomatous. Cases have been reported in which the primary lesion of syphilis has developed on the site of an old scabies lesion, or in which a herpes preputialis has been followed by a definite indurated chancre. The report of such a case may be of interest:

Case I.—Andrew L., age 28, born in United States. Seen first in April, 1905, with herpes preputialis, on dorsal surface of the foreskin. While under treatment the patient became exposed to syphilitic infection, and about three weeks later, a typical indurated chancre developed on the site of the treated herpes. This was followed in due time by general adenopathy and the secondary roseola. Here, then, we had the two conditions existing conjointly, the herpetic lesion being the avenue of entrance of the specific virus.

Psoriasis is particularly liable to have pseudo-transitions occurring in the natural course of the disease. The following case is a pertinent example:

Case II.—Rebecca H., age 20, native of Russia. In September, 1902, the patient was first admitted to clinic, suffering from an acute generalized psoriasis. The disease, under dispensary treatment, improved for a time, but in 1905 the condition seemed to come to a standstill, and the patient was admitted to the hospital. Here she has remained for two years, with intermittent outbreaks of the disease. Periods of quiescence, with apparent clearing up of the symptoms, would be followed by a very acute attack, during which hardly a square inch of the patient's body would be free from lesions. During one of these exacerbations, following the appearance of large hypertrophic plaques, almost verrucous in nature, the patient developed an acute exfoliative condition, which was most marked on the back. Papery scales, the size of a dime, were thrown off in abundance, leaving a shiny, red, florid surface, similar to that seen in pityriasis rubra. Under emollient treatment, small islands of normal skin appeared, the florid appearance became considerably lessened and finally cleared entirely, leaving only the generalized psoriasis.

Here, then, we had a change, occurring in the natural course of the disease, strongly simulating another condition, while the clinical manifestations of psoriasis continued as before. It could be termed a pityriasiform psoriasis, and may possibly have been caused by a too free or too strong application of chrysarobin.

Cases have been reported of pemphigus foliaceus, terminating in dermatitis exfoliativa; of ichthyosis hystrix changing into pityriasis rubra; of lichen planus developing into generalized exfoliative dermatitis. These changes were probably due to over-treatment. Too free use of mercury in lichen planus, chrysarobin in psoriasis, or sulphur in scabies will oftentimes produce lesions simulating pityriasis rubra very closely.

True Transitions.—Occasionally, however, we find cases in which true transitions have undoubtedly taken place. By the term "true transition" we mean a gradual evolution of one process or disease into another, without any clearly defined boundary line to indicate where one process begins and the other ends. This may be exemplified in a variety of conditions:

1. Eczema, pemphigus, or psoriasis changing into pityriasis rubra—the further evolution of this condition into mycosis fungoides.
2. The transition of eczema seborrhœicum into mycosis fungoides.
3. The change of urticaria, pruritus, or eczema into dermatitis herpetiformis.
4. Eczema of the nipple into Paget's disease.
5. Rosacea into rhinophyma.
6. Senile wart into epithelioma.
7. Specific glossitis or tubercular syphilide into carcinoma.
8. Transitory changes in xeroderma pigmentosa.
9. Transitory changes in Sailor's skin disease.
10. Transitory changes in kraurosis vulvæ.

These, then, are examples of true transitions. The eczema, psoriasis, urticaria, or rosacea continues for a time a more or less natural course. Then there supervenes a period of activity—the condition becomes more acute, and suddenly we realize that a new condition is thrusting itself upon us; that the original disease, although possibly still active, is being encroached upon, replaced and gradually eliminated by an entirely new condition, having an entirely new chain of symptoms, and differing from the former, both clinically and morphologically. This can possibly be exemplified by citing a few cases which came under my notice during my service at the New York Skin and Cancer Hospital.

The Change of Eczema into Pityriasis Rubra of Hebra.

Case III.—Anna D., age 60, born in Ireland. In September, 1903, the patient first had a mild attack of eczema, involving the back and extremities. This later became worse, rapidly spread, and soon involved the whole skin. The patient had chills, fever, delirium, etc., and "could not get on enough bedclothes, even on a hot summer's day." There were marked intermissions, and the patient occasionally became much improved. In May, 1905, she entered

*Two cases reported by Pringle.

the hospital. The skin was thickened, scaly, infiltrated, and reddened, and marked contractions around the eyes were evident. Sometimes quantities of serum would exude. Large quantities of penny-sized scales were scattered over everything if the patient remained in the same position for any appreciable time. The condition gradually became worse, until the patient died in November, 1905, of pulmonary edema. This case starting as a simple eczema, grew gradually worse. A new condition was evolved, having all the classical symptoms of pityriasis rubra, which led to a fatal termination.

Transitions into Mycosis Fungoides: Stages: Psoriasis (?), Eczema, Pityriasis Rubra, Mycosis Fungoides.

Case IV.—John H., age 45, native of Germany. In 1904 while in Germany the patient had psoriasis, the diagnosis being made by a reputable dermatologist in Hamburg. He came to America in 1905, and entered the hospital in March of the same year, suffering from a generalized eczema. This rapidly grew worse; the skin became thickened, infiltrated, and reddened, and two months later the patient manifested intense itching, chills, and fever—all the indications of an acute attack of pityriasis rubra. In May of the same year, tumors and ulcers appeared on the chest and back, and the diagnosis of mycosis fungoides was made. This was subsequently confirmed by pathological examination. The tumefaction and ulceration were held in check by the *x*-ray, the ulcers healing rapidly under its influence until August of the same year, when four large, deep ulcers appeared on the scalp. These yielded readily to the *x*-ray treatment, however. From this time the predominant symptom was intense itching, accompanied by the usual premycotic eczematoid condition, and marked exfoliation. The premycotic eczema still continued with no abatement of symptoms, and with the constant appearance of tumors and ulcers, until the patient died of asthenia in January, 1906.

Eczema Seborrhœicum, Pityriasis Rubra, Mycosis Fungoides.

Case V.—Bessie F., age 30, born in Russia. In June, 1904, the patient was first troubled with a falling out of the hair, accompanied apparently by an eczema seborrhœicum of the scalp. This continued and was soon followed by chills and fever, which lasted for two days, after which erythematous scaly patches appeared all over the body. These spots continued to form, became larger and coalesced. Scales, large and thick, began to accumulate, and the skin became thickened, hard and dry, and slightly drawn. In December, 1904, symptoms typical of pityriasis rubra appeared. There began a profuse exfoliation. On moving about, the patient produced a very shower of small dime-sized scales. This exfoliation was accompanied by chills, nausea, and delirium, while the contractions about the eyes became more marked. The diagnosis of pityriasis rubra was made and confirmed by a microscopical examination of a section of the diseased skin. During this time, considerable itching and burning was manifested, although no scratch marks were evident. Several ulcers appeared over the body, face, and limbs, very superficial and circumscribed, with borders clear cut, and covered closely with a thick, brownish crust. The integument became absolutely devoid of hair. The nails thickened, especially at their extremities, and became increasingly brittle. This condition of affairs continued for three months, with marked intermissions. Fresh outbreaks occurred at more frequent intervals, accompanied by terrific headaches, faintness, and general malaise. The pruritus still continued as the dominant symptom, relieved only by long daily exposures to the *x*-ray. In March, 1905, from small tumefactions then appearing, the diagnosis of mycosis fungoides was made, and this was confirmed at the time by examination of the pathologist. Urticaria-like spots, really premycotic lesions, constantly appeared, and were held in check and gradually melted by the *x*-ray applications alone. Left for a week without *x*-ray exposures, the patient would have a fresh outbreak of these lesions, and these, protected from the action of the rays by thick coverings of tinfoil, resulted in typical mycotic tumors. Exacerbations became increasingly frequent, attacks of faintness, malaise and general depressions more marked. During a period of quiescence in June, 1906, the patient left the hospital. She died three weeks later, endocarditis being noted as the cause of death.

Eczema Seborrhœicum—Mycosis Fungoides.

Case VI.—Lars E., age 46, born in Norway. The patient was first seen in March, 1906, with a typical seborrheic eczema of the scalp, chest, and inguinal folds. Late in April, and in the early part of May of the same year, lesions were noticed to appear first on the genitals as tumor masses, pigmented spots, and infiltrated, thickened, itchy patches. These were at this time recognized by three different dermatologists as manifestations of a true case of mycosis fungoides. This condition soon became generalized, and pruritus was unmodified by any of the ordinary antipruritic remedies. Under general dietetic and local treatment the constitutional condition improved, and the tumors gradually melted. The patient was discharged in an apparently normal condition, and resumed work as a laborer, with no recurrence as yet.

Allowing the possible inaccuracy in the diagnosis of psoriasis in Case IV., we still have two marked and distinct transitions—the eczema into pityriasis rubra, and the pityriasis rubra into mycosis fungoides while under observation in hospital. In Cases III., V., and VI. the changes were undoubted, and were verified by careful pathological examination.

One will notice at a glance the apparent importance of the *x*-ray treatment in allaying the itching, and causing a general subsidence of these conditions, particularly in the mycotic stage. Some have stated even that the *x*-ray is almost a specific in this condition. This I doubt, for, although patients have improved considerably under its influence, although tumors have melted, and the pruritus has been lessened, yet, in the later stages of Cases IV. and V., a gradual decline in general vitality was noticed, and the patients gradually failed from inroads of the disease, despite long daily exposures to the *x*-ray.

Urticaria and Eczema Changing into Dermatitis Herpetiformis.

Case VII.—John R., age 14, born in United States. As a child, the patient was brought up on the bottle, the mother not having sufficient milk to support the child. He was a strong, vigorous child, and was allowed to appease his appetite at every feeding. At the age of three months, an eczema of the infantile type appeared first on the face, and afterward over the body generally. This condition, in spite of treatment, continued, became chronic, attacks occurring intermittently throughout a period of thirteen years. In May, 1905, the patient suffered from eczema orbicularis, which cleared up under a few weeks' treatment. The generalized eczema continued to break out at intervals, however, responding satisfactorily to treatment until June, 1906,

when it began to disappear. The fading of the eczema was only preliminary to the advent of a new condition. Vesicles occurring in groups, rising from a distinctly inflammatory base, began to appear on the back, chest, and extremities. The lesions were definitely herpetic in nature, and were accompanied by an intense pruritus. There was no involvement of the scalp or of the mucous membrane of the mouth, and the face was comparatively free. Blood examination revealed an eosinophilia, but otherwise the blood condition was normal. The condition was now recognized to be dermatitis herpetiformis, having all the classical symptoms of that disease, the preexisting eczema having entirely disappeared.

Urticaria, as we all know, is a very common antecedent of dermatitis herpetiformis. The latter condition is almost always subsequent to one of that class of symptoms indicative of an autointoxication, *e.g.* graphodermia, urticaria, or erythema multiforme. Some observers, in fact, believe these to be merely clinical manifestations of the disease itself, and not entities, as is generally supposed.

Paget's Disease—Carcinoma.—The surgeon and dermatologist frequently confer regarding the condition known as "Paget's Disease." The lesion is usually found involving the nipple and areola. Considerable pruritus is experienced, necessitating sometimes constant scratching. Oftener, however, the pruritus is less intense; a fissured condition presents itself, accompanied by considerable oozing of serum, which often forms thick crusts. On the removal of these crusts, a red granular base is exposed, and a definite hardness is felt around the site of the lesion. Sooner or later we find a nodular growth in the breast tissues truly carcinomatous in nature.

Case VIII.—Lydia R., age 48, born in Germany, unmarried. The patient has been in America fifteen years. There is no hereditary history of cancer and no traumatic history. One year ago the patient noticed a slight redness of the right nipple shading faintly into the surrounding skin. A few weeks later fissures appeared on the sides of the nipple, a serous exudate appeared, forming thick impetigenous crusts. At that time the patient noticed no induration around the site of the lesion, and little or no pruritus was experienced. Seen in our dispensary in March, 1905, the patient suffered from considerable pruritus. On the removal of the thick crusts around the nipple, a red granular base was exposed, giving to the touch the "coin under a cloth" feeling, typical of Paget's disease. Having left the city, the patient was not seen until ten months later, when definite carcinomatous nodules were felt in the breast; the skin over the tumors was reddened and fixed, and had the typical "pig-skin" appearance. Involved glands in the axilla and along the outer border of the greater pectoral muscle, were easily palpated. The patient refused operation and disappeared.

Case IX.—Margaret F., age 80, born in Germany, occupation housewife. The patient has always been healthy and was the mother of four children, all of whom she has outlived. In March, 1902, the patient noticed a slight redness of the left nipple and areola, but experienced no pruritus. This, under local applications, cleared up at times, but early in May, 1906, the redness recurred. This time, too, no pruritus was experienced. The redness and slight induration proved resistant to any form of local treatment, and when the patient presented herself in the dispensary in August, 1906, the lesion was already ulcerative. It was thickly covered by a heavy crust, and on the removal of the same, a red granular-looking surface was exposed. Immediately below, and to the outer side of the nipple, an indurated globular tumor was made out, and this was firmly adherent to the adjacent skin. No glands could be palpated in the axilla. Amputation of the breast one week later disclosed a tumor which the pathologist reported as true cacinoma, on microscopical examination.

Rosacea—Rhinophyma.—Rosacea, or acne rosacea, as it is sometimes called, also presents transitory changes throughout its course. Primarily is noticed an hyperemia of the skin in some part of the middle of the face—the forehead, nose, cheeks, or chin. Within the inflamed area, acne-like nodules develop, which eventually become pustular. This continued hyperemia leads to an increased development of fibrous tissue, which gives a feeling of thickness to the involved areas. Allowed to continue, large fibrous, pendulous masses often develop, giving to the nose an irregular potato-like appearance, and to the other areas the leonine expression of nodular leprosy. A case of mine, seen in practice, is illustrative:

Case X.—Bridget M., age 58, born in Ireland, occupation news-vendor. For eleven years the patient had suffered from a diffuse redness of the middle part of the face, interspersed with small lumpy protuberances. She had been subject to acute indigestion, severe eructations of gas being the dominant symptom. The patient has always been moderately alcoholic until recent years, when stimulants have been indulged in more frequently than usual. Her occupation as news-vendor necessitated constant exposure to the weather and the patient believes this to have been an etiological factor in the production of the rhinophymatous condition present, when first seen. Seen by me in December, 1906, the patient presented all the indications of rhinophyma. The forehead, inner parts of the cheeks, nose, and chin were thickened and reddened, evidences of the preexisting rosacea. The nose was enlarged to about twice its normal size. From the left ala nasi protruded several tumor masses, some pedunculated, others merely excessive thickenings of the skin itself. Over the thickened reddened area on the forehead were to be seen oily scales peculiar to seborrhœa oleosa. Under local and constitutional treatment slight improvement was noted.

Senile Wart—Epithelioma.—Surgeons who operate cancer extensively have observed from time to time the occurrence and development of epitheliomata from senile warts. On the average individual over the age of sixty, suffering from epithelioma or carcinoma, we find freely distributed over the exposed parts, rough, warty protuberances. These are peculiar to old people, and with or without irritation, they subsequently develop into epitheliomata. Many individuals exhibit a definite epitheliomatous "diathesis" in this respect.

Specific Glossitis—Carcinoma.

Case XI.—Patrick O., age 46, native of Ireland. The patient contracted syphilis at the age of 35, the disease running its natural course without any vigorous treatment. The usual symptoms of night headaches and pain in the bones were experienced. The patient was first seen in the dispensary in September, 1906. At that time there were multiple small specific cicatrices on the forehead. The tongue was indurated and tender, while numerous mucous patches were seen in the mouth. The right submaxillary and right cervical glands were considerably enlarged and tender. There was also considerable salivation. Over a circular area about four inches in diameter, and located just below the lower

right costal border, was seen a rupial florid-appearing lesion, described by Sabouraud as the "syphilitic bouquet." Under mixed treatment the lesions improved for a time. The rupial lesion cleared up, leaving a dull purple-colored scar. The tongue seemed less indurated, but the cervical glands remained the same. A fortnight later the condition grew worse. The tongue became hard and sore, being seamed with fissures peculiar to specific glossitis. The cervical glands became increasingly hard, and soon the floor of the mouth was involved, the whole mass becoming matted together, and practically immovable. The secretion of saliva became profuse, causing the patient no little discomfort. In November, 1906, a biopsy specimen was taken from the tongue and the pathologist reported carcinoma at once, advising immediate removal. Surgeons pronounced the case inoperable, advising palliative measures for his few remaining days.

Case XII.—Peter S., age 52, native of Germany. The patient contracted syphilis at the age of 28, the disease running its regular course without medical attention. In May, 1906, the tongue first grew hard and sore. The patient had previously had mucous patches in the mouth, but no tongue involvement. Marked salivation was an early symptom, which increased and was accompanied by a putrid odor. In this condition the patient was admitted to the dispensary in June, 1906. Ordinary antisyphilitic treatment produced no results, and soon the suspicion of a more malignant condition was aroused. The glands of the neck became involved and hardened. On the surgeon's advice the tongue was removed (Kocher's operation), and the glands of the neck were thoroughly cleaned out. Pathological examination of the diseased tissue disclosed the presence of true carcinoma.

Transitions in Lesions.—No more striking example of "true transition" can be found than the transitory changes in xeroderma pigmentosa. Unna describes this condition as beginning as an inflammatory hyperemia and freckle-like collection of protective brown pigment, while shining mother-of-pearl spots appear between the pigmented areas—a definite sclerosis. A roughness of the skin is noticed early in the disease. This is due to innumerable small verrucous foci, which soon develop into definite warty protuberances, and finally become either true or pigmented carcinomata. Here then we have primarily an inflammatory hyperemia. From this there develop warty growths which finally assume the form of carcinomata.

Similarly, too, Unna, in describing the condition termed "sailor's skin disease," says: "To the first stage of erythema, pigmentation or hyperkeratosis there succeeds a further one. Large wart-like growths appear, hypertrophy of sebaceous glands, and papillary ulcerating carcinomata are the end results." So, too, in kraurosis vulvæ we primarily have an intense pruritus. Then an eczema develops. Later tumefaction and malignancy are the final results.

In the above group we have transitions not from one disease into another, but from one lesion into another, each part and parcel of the same disease.

There may also be found a series of intervening cases, neither "true" nor "false" in transitory change, but simply one condition may precede another with such marked frequency that one might easily consider it a true definite transition.

Bulkley, in his Boston paper before the American Medical Association, made the remarkable statement that a very large percentage of his cases of psoriasis in private practice were preceded by one or more attacks of dermatitis seborrhœicum. He does not consider this a transition, but thinks that the soil most favorable for the development of eczema seborrhœicum is also most suitable for the appearance of psoriasis. In short, individuals predisposed to the one condition are invariably predisposed to the other, the seborrheic element being the first to appear. It is remarkable how very difficult it is—at times impossible—in border-line conditions, to say definitely whether lesions are to be classed as psoriasis or eczema seborrhœicum. The correlation is noteworthy.

Norman Walker, on the other hand, is very emphatic in his belief that here we have a definite transition. He claims that no sharp line of demarcation can be drawn, and that eczema seborrhœicum is the natural antecendent of psoriasis in many instances.

Observers have noted from time to time the frequency with which seborrheic eczema has preceded acne rosacea. Antecedent to the hyperemic stage one very often finds oily seborrheic scales covering the area subsequently involved. Some dermatologists believe the seborrhea to be an etiological factor in the production of the rosacea.

Then, too, in prurigo we find pruritus or urticaria preceding the condition so commonly, that many writers have come to believe that the papule of prurigo is not due to the inherent disease, but to the scratching attendant upon the severe pruritus—purely a secondary condition.

These are but a few meager examples of dermatological transitions. The changes are varied and innumerable, necessitating careful study and patient observation. It is to be hoped that a more general acceptance of the term "transition" may lead to a fuller recognition of the correlation of skin diseases, a more careful study of their common cause, *i.e.* metabolic derangement; and last, but not least, a simplifying of the nomenclature.

CRIMINAL ASPECT OF VENEREAL DISEASES IN CHILDREN.*

BASED UPON THE PERSONAL EXAMINATION OF OVER 900 CHILDREN, THE ALLEGED VICTIMS OF RAPE, SODOMY, INDECENT ASSAULT, ETC.

By W. TRAVIS GIBB, B.S., M.D.,

NEW YORK

VISITING SURGEON, WORKHOUSE, ALMSHOUSE AND PENITENTIARY HOSPITALS, BLACKWELL'S ISLAND; CONSULTING SURGEON, KINGS COUNTY PENITENTIARY HOSPITAL; EXAMINING PHYSICIAN, NEW YORK SOCIETY FOR THE PREVENTION OF CRUELTY TO CHILDREN, ETC.

Sexual crimes against children of tender years are much more prevalent in our great city than many of our profession are aware, and no one, not intimately connected with a great society which has in its charge the physical and moral well-being of children, can realize the vast amount of misery these helpless infants are compelled to suffer through the ignorance, cupidity, carelessness, and brutality of men and women, and frequently the worst of these offenders are the very ones who naturally ought to protect those who become their victims. This is a sad condition of affairs, but we have in our city a large cosmopolitan population, many of them coming from foreign countries where childhood is not as sacred as with us, or where children, maturing at an earlier age, have the vicissitudes of adult life forced upon

*Read before the American Society of Sanitary and Moral Prophylaxis, October 11, 1906, and the Pennsylvania Society for the Study and Prevention of Social Disease, December 20, 1906.

them sooner than in this country. Such people, bringing their foreign ideas here, commit acts which are considered criminal in this country, but which, in their native lands, would be looked upon with indifference.

Many of these crimes are undoubtedly committed by sexual perverts whose vagaries are such that they can only be regarded as emanating from an insane mind. I have seen this exemplified in many instances, one of which I may be permitted to cite: A big, lusty Italian raped his eight-months old infant, tearing through the perineum and recto-vaginal septum to such a degree that an extensive plastic operation was necessary to repair the damage. His efforts were so violent that he abraded and excoriated his glans penis so that the injuries were apparent when I examined him a number of days after the crime. He assured me that he had been instructed by God to commit the act in order to save his child's soul. The man was undoubtedly insane and was so declared by a committee and sent to an asylum for criminal insane.

Intoxication is another cause, or rather excuse for many of these crimes. It has been brought to my notice many times that among certain classes, especially ignorant Italians, Chinese, and Negroes, it is an accepted belief that if a man, afflicted with an obstinate venereal disease have intercourse with a virgin, the latter will develop the disease and he will be cured. This belief is responsible for many of the cases of venereal diseases among children which come to our notice.

A fairly large proportion of the rape cases which I have examined occur in girls between the ages of twelve and sixteen, where the child is the willing victim, and in many of these cases the children are so precocious that if the law as to the age of consent was not perfectly explicit it would be extremely difficult to secure the punishment of the perpetrator of the act. If we take into consideration the moral and physical environments under which these children are raised it is not at all surprising that their standards of morality are so exceedingly low. These children are herded in crowded tenements where it frequently happens that in addition to the family in the small apartment, boarders or lodgers are taken and the quarters are so cramped that there can be no decent privacy for anyone. The boarder or lodger in a crowded tenement apartment is a very frequent offender in the rape cases I have seen. In addition to this crowded condition of their homes, the low moral standard of the parents and guardians has much to do toward familiarizing the children with the immoral side of life. I am reminded of a case, and this is one of many, where three children were removed from the home of a longshoreman on the grounds that the children's morals were endangered. The man was accustomed to cohabit with his wife in the presence of his children whenever he was inclined. Is it to be expected that children raised amid such surroundings would develop very exalted moral ideas?

This low standard of morality affects children even of a very tender age, and in some instances girls of nine or ten years, and even younger, have been found with abnormally developed sexual instincts, and they often submit willingly, usually for pay, to the man whose perverted instincts leads him to choose a very young child for the gratification of his sexual desires. It is horribly pathetic to learn how far a nickel or a quarter will go toward purchasing the virtue of these children.

It is no uncommon occurrence for the father of a child to be charged with that most revolting and heinous of all crimes—incest. Within the past two weeks I examined a negro girl, eight years of age, suffering from gonorrhea, whose father was accused of raping her. I know of many instances where a father has used his daughters for his sexual gratification one after another as they grew large enough to permit his advances. The majority of these cases have occurred among Germans of the lowest class, and the defense of the accused man was usually that he thought he had a right to do as he pleased with his own children, and he resented the action of the authorities in stopping the practice and punishing him as an encroachment upon his rights.

I have been connected with the New York Society for the Prevention of Cruelty to Children for the past fifteen years as examining physician, and in that capacity have examined over eight hundred girls upon whom it was alleged the crime of rape had been committed, and about one hundred girls and boys the alleged victims of sodomy, indecent assault, and other sexual and unnatural crimes. These children were from eight months to sixteen years of age; the latter age being the age of consent under the old law in this State. This age of consent has recently been raised to eighteen years, but as the Society was organized for the protection of children under the age of sixteen, it does not lend its aid in the investigation and prosecution of cases where the alleged victim is beyond the age of sixteen. The city authorities have charge of the investigation and prosecution of all rape cases where the complainant is between sixteen and eighteen years of age, and the scarcity of such cases which are brought to trial in comparison with the number where the complainants are between fourteen and sixteen, where the investigation and prosecution are under the supervision of the officers of the Society for the Prevention of Cruelty to Children, exemplifies to a marked extent the efficiency of that society, for it must be admitted that rape is more liable to occur in girls between sixteen and eighteen than in those between fourteen and sixteen.

In the examination of these nine hundred children I found that in about 33 per cent. there was absolutely no physical evidence that there had been any violation of their persons. Their hymens were intact, and there were no evidences of contusions, abrasions, excoriations, or discharges upon or about the genitalia which might have been caused by an act of violence. All suspicious discharges are examined microscopically and if gonorrhea exists an effort is made to secure an examination of the accused.

In 17 per cent. of the cases there were evidences of complete and recent penetration. In other words, the tears in the hymen or fourchette, the abrasions, contusions, etc., of the mucous membranes and neighboring soft parts had not had time to heal between the time of the commission of the alleged crime and my examination.

In exactly 50 per cent. of the cases there was evidence of complete, though not recent, penetration of the genital organs by some blunt object. All the injuries, tears, stretching, abrasions, and contusions had had sufficient time to heal between the first penetration and my examination, and there remained absolutely no physical evidence to show whether the assault had occurred ten days or ten months previously.

In view of the fact that the subject under discussion is venereal diseases as affecting children and not sexual crimes upon children, a discussion of the methods and results of my examinations in

these cases, except where venereal diseases were present, would be out of order.

In my examination of these nine hundred cases of alleged sexual crimes upon children I found that almost 13 per cent. of all the children examined, or 117 children, were suffering from venereal diseases in some form. Of these, 81, or about 9 per cent., had gonorrheal vaginitis, vulvitis, or urethritis. The macroscopical appearance in each case was verified by finding the gonococcus in a stained specimen of the discharge obtained at the time of the examination. Two and one-half per cent. of the children had chancroidal ulcerations involving some portion of the genital tract or anus. These ulcers varied in number from one to a dozen or more. In about 1 per cent. there were venereal warts. There were three cases of gonarthritis and two of gonorrheal infection of the rectum in boys.

I have been surprised at the very small number of cases of syphilis found among the 900 children I have examined. Not over two or three cases have been noted in the whole list. The apparent rarity of this ordinarily common form of venereal disease is due in my opinion to the fact that the children are usually examined within a very short time after the commission of the alleged crime, and sufficient time has not elapsed for the development of the characteristic lesions of the disease. I seldom see the children after my examination until the trial of the accused takes place, and the cases are frequently disposed of entirely within such a short time that if the disease develops at all it makes its appearance after the child has left the care of the Society.

All the children entering the Society's care are bathed before they are allowed to mingle with the other inmates. The bathroom attendant is trained to note any abnormal condition and report to the nurse in charge. All suspicious cases are at once isolated, and a medical examination is made. Should the child be found to have a venereal disease it is transferred as soon as possible to a suitable hospital for treatment. The very small children are sent to St. Mary's Hospital for Children, where they receive the most excellent care and treatment and are returned to the care of the Society when cured.

The older children, especially the girls, are usually sent to the venereal wards of the City Hospital on Blackwell's Island and occasionally to some of the other hospitals which will receive them. It is a deplorable condition of affairs which renders it necessary to send children of tender age, suffering from loathsome diseases, for treatment to the wards of a public hospital where they are brought in contact with the most abandoned and degraded members of their sex, and whatever of wickedness and depravity they may not have learned before, they are apt to acquire during their stay in the hospital. The young girls are frequently very proud of the fact that they have been in what is popularly known as the "vaginitis wards," and it is quite a mark of distinction when they return to the Society.

There is another condition in reference to children to which I would like to call attention. I have been told by a number of dispensary physicians that they treat venereal diseases in children with a fair degree of frequency. While it is possible that such diseases may be transmitted through infected clothes, water closets, etc., the majority of them, it must be admitted, are the results of criminal assaults, and the doctors' examinations are frequently the first intimation the parents or guardians may have that such an assault has occurred. I would strongly urge that all such suspicious cases, and also all cases of pregnancy in unmarried girls under the legal age of consent, be reported to the proper authorities for full investigation. Where the disease was contracted accidentally no harm would be done, but where a crime has been committed the perpetrator might be unearthed and brought to justice, when otherwise he might escape.

Recently within a single week I examined five girls, all under eight years of age and suffering from gonorrheal vaginitis and vulvitis. In three of the cases the accused was a Chinaman, in another an Italian, and in the last the child's father, a negro, —was the accused. In all the cases permission to examine the accused was denied.

In a number of cases in which I have found the victim of an alleged assault suffering from a venereal disease, an examination of the accused revealed that he had absolutely no evidence of the disease. Of course, an investigation is always made in such cases to ascertain whether the accused might not have had the venereal disease in question at the time of the alleged assault, and been cured before the examination was made. The absence of any evidence that he has or has had the disease I have always considered good proof that he did not infect her. If, however, the accused is found to be suffering from the same venereal disease as the victim, the medical evidence is very damaging.

In these 117 cases of venereal disease among the children I have examined, the nationalities of the accused were about as follows: Italian 29, Chinese 25, German and Hebrew 16, Irish 5, Greek 4, Polish Hebrews 4, colored 4, United States 2, not stated 18.

The ages of the children affected with venereal diseases varied from three to sixteen years. I found two children three years of age suffering from gonorrhea of criminal origin; fifty-eight were under ten years of age, and thirty-six were between fifteen and sixteen.

These nine hundred cases examined represented something more than half the total number of examinations made for the Society in this class of cases during the past fifteen years. There are many more cases of alleged sexual crimes against children brought to the notice of the Society, but the examining physicians see only those cases in which, in the opinion of the city magistrate, there is sufficient corroborative evidence to warrant an examination.

In spite of this large number of cases which have been brought to the attention of the Society, I am of the opinion that they are but a small proportion of the cases of sexual crimes against children which actually occur in our city. In a large majority of the cases the children themselves never tell what has happened to them, and again the fear of publicity, the effects of such publicity upon the children and their future, and the dread of placing their children in the care of the authorities are dominant factors in deterring many parents and guardians from making criminal charges when they find their children the victims of such sexual crimes, especially when the injury is more moral than physical.

It is seldom that children of the better classes are the complainants in the prosecution of these cases. Undoubtedly these crimes occur among the well-to-do, but the parents of these children are very loath to endure the unpleasant notoriety which is sure to accompany the prosecution of such a charge.

The amount of sexual crime perpetrated upon children in our city is enormous and is largely due to the crowded conditions under which the poorer classes live. In addition, there is the superstition and dense ignorance of our large foreign population, the brutality, perversion, and intemperance of many of

the alleged perpetrators, and the precocity and low moral standard of many of the child victims.

Since this paper was written, a little more than a month ago, I have examined sixteen girls for rape, three of whom, aged respectively eight, ten, and eleven years, were suffering from gonorrhea. One of these cases was particularly interesting from a medicolegal standpoint.

On November 12, two days after the alleged crime, I examined the eleven-year-old girl and found her hymen intact, with an orifice 12 mm. in diameter; there were no contusions or abrasions, and not the slightest evidence of discharge. I gave a certificate that in my opinion there was no physical evidence that a criminal assault had been perpetrated upon her. The corroborating evidence was slight and the case was disposed of in court by the discharge of the accused, and the child left the charge of the Society three days after my examination. About December 1, eighteen days after my examination and twenty days after the alleged assault, the mother noticed that the child's garments were stained by some vaginal discharge. She was taken to a dispensary for treatment and a few days later, because the child refused to take her medicine, the mother beat her severely with a strap, producing a number of contusions upon her thighs and legs. On December 8 she became very ill and was taken to a hospital where it was found she was suffering from severe abdominal pains and great tenderness. Finding the child severely bruised and learning that there had been an alleged assault, the physicians examined the vaginal discharge and found it to be due to gonorrhea. The hospital authorities at once notified the coroner who ordered the immediate rearrest of the alleged assailant. An examination of his penis by the hospital doctors failed to reveal the slightest evidence of gonorrhea.

I was directed to see the child and on December 10 found her to be suffering from a gonorrheal vaginitis, together with a peritonitis involving the entire right side of the abdomen, extending to the free border of the ribs. The pain, tenderness, and tension were most marked over the region of the appendix. I examined the man and failed to find gonococci.

In this case the gonorrhea developed almost three weeks after the alleged assault. In the meantime the mother had beaten the child severely, the accused man had absolutely no indication of gonorrhea, and the child developed a condition which resembled very closely an attack of acute appendicitis. The child recovered, but it would be interesting to know in the case of the child's death who would have been held responsible.

OBSERVATIONS ON THE TREATMENT OF TUBERCULOSIS IN ARIZONA.

By ISAAC W. BREWER, M.D.,

FORT HUACHUCA, ARIZONA

Every winter brings a host of persons with tuberculosis to Arizona and New Mexico. A considerable proportion of them recover or improve, while not a few do badly, and either die or remove to some other portion of the country, hoping to be benefited by the change. Without doubt the climate of the Southwest, with its low humidity, abundance of sunshine, and mild winters, is a most favorable factor in the treatment of tuberculosis; but a study of the condition of the Indians in that region will convince anyone that climate alone will neither cure nor prevent the disease.

In this paper it is my intention to consider what appear to be the reasons why some of the patients sent to the Southwest fail to obtain any benefit from a sojourn in that region, and then to give some general information about the climate and accommodations that are to be found in the territories. These remarks are based upon experience with a few cases that have come under my care in this region and upon conversations with physicians, and with patients suffering with the disease whom I have met in different portions of the Southwest.

One of the principal causes of failure is lack of proper food. Physicians in the East do not appreciate that very little of the food supply of the Southwest is grown in that region. As a rule, almost everything is imported from Southern California or the East, and, owing to the excessive freight rates, everything is very high. The charge on a box of fruit from Southern California to Fort Huachuca generally equals, and frequently exceeds the original cost in the Los Angeles market. Butter is generally forty cents a pound, milk ten cents a quart, eggs from thirty to sixty cents a dozen, and other staples correspondingly high. The native beef is often tough and stringy, although in some of the large towns alfalfa beef from the Salt River Valley can be had. This is probably the best beef in the country. For persons with plenty of money these figures mean nothing, but for those in moderate circumstances they are prohibitory. Around Phœnix the conditions are somewhat better, as the local markets are largely supplied from the surrounding farms.

In order to overcome the high prices it is not uncommon to find invalids economizing either by cooking their own food or by taking their meals at some cheap restaurant. In the first case their food is badly cooked, and in the latter instance the quality is generally poor, and the service is always bad.

My experience with boarding houses has been limited, and my information is largely second hand. At most of the resorts there are satisfactory accommodations of this class, but the number is limited. One great disadvantage in them is that a large number of persons are thrown together without proper supervision, and not infrequently they become morbid and despondent. Constant discussion of symptoms does not encourage the sufferer, especially during the early days of his sojourn.

There are few, if any, first-class hotels in this region. This is partly due to the difficulty in obtaining competent help and partly to the cost of food supplies. Most of the hotels do not take "consumptives," which means that they do not take cases that are far advanced. I have not seen a hotel in this region that did not have one or more persons with tuberculosis among their permanent boarders. The rates at the best houses are from three to five dollars per day.

Lack of Congenial Society.—Dr. Norman Bridge of Los Angeles, speaking of the climatic treatment of tuberculosis, says: "The patient in any climate must be properly fed, housed, and warmed. . . .

It is just as important that he should have contentment and mental peace. . . . . I would rather have a patient kept in the outskirts of an Eastern city (or in the heart of the city), under good hygienic management, sleeping in the best air obtainable winter and summer, and with friends and comforts about him, than to send him to some better climate to shift for himself and be lonesome and homesick." These words from a man who has had a large experience with the treatment of tuberculosis should be remembered by every physician before

he sends his patient among strangers to some remote region to obtain the problematic benefits of climate. Not a few persons who come here suffer from nostalgia. Especially is this the case with city bred men who have been used to the hurry of modern business life. They are liable to find fault with everything and to consider their sojourn in the West as a banishment. Such persons always do badly. Those who cannot adapt themselves to new conditions had better stay away. If your patient be despondent, keep him at home.

Many consumptives come to this region having been instructed by their home physician to leave medicines and physicians alone and to live in the open and "rough it." This is about as pernicious advice as can be given. The patient's first duty is to consult some local physician. He will thereby be saved considerable expense and annoyance and will start properly. The physicians in this region are forced to pay particular attention to tuberculosis, and, besides the usual interest that physicians take in their patients, many of them having had the disease have a fellow feeling for the sufferer.

Few, if any, tuberculous persons have the strength to "rough it" when they first arrive here. The increased altitude causes an extra strain on the heart and lungs, and until compensation is established most persons suffer from more or less shortness of breath. They should therefore be quiet until they have become used to the climate and the altitude.

If, after becoming acclimated, one desires to try camp life, and the local physician considers him physically able to endure its hardships, he may procure several Munson tents, a competent guide, and saddle and pack animals, and shift his camp from place to place as the season advances, going north to the region of the Black Mesa or Flagstaff in the summer, and returning to Tucson, or the Salt River Valley in the vicinity of Phœnix, in the winter. The tents will rarely be used excepting in bad weather, for during the greater part of the summer and fall it will be possible to sleep in the open. There are many charms to such an outing. It is devoid of monotony, and hunting and fishing may be enjoyed in the mountains. The region traversed is filled with prehistoric ruins, especially the valley of the Verde and around Flagstaff. On such a trip the food will be necessarily confined to canned vegetables and fruits, and bacon will constitute a large portion of the meat ration.

There are a number of tent colonies in Arizona, and, if under proper medical supervision, they are excellent. Being cheaper than other accommodations, they are available for those in moderate circumstances. Many of them unfortunately are not properly laid out, and the tents are often close and badly ventilated. The practice of wainscoting tents is objectionable, as it reduces the amount of fresh air that can be admitted.

Tents should be pitched so that they will be shaded during a portion of the day. It is well to have them face the east, so that they can be flooded with sunlight as soon as vacated in the morning. They should be provided with board floors made in small sections that can be readily removed so as the space beneath may be kept clean. They should never remain on the same ground for more than five days at a time; at the end of that time they should be moved so that the ground may be thoroughly disinfected by the direct rays of the sun.

In rainy weather tents become cold and clammy, and to obviate this a small stove is often used. Some of the camps that have come under my notice have been badly conducted from a sanitary point of view.

As regards exercise, many physicians have erroneous ideas. Being used to the overfed business man who leads a sedentary life, they think all persons should take as much exercise as possible. We encounter many persons who have been sent here and told to procure a horse and ride as much as possible. Every physician who has had any experience with tuberculosis in this region well knows that the new comer should rest for a considerable time after his arrival. He may then begin to do a little walking, and later may indulge in horseback riding if his condition warrants it. A physician in an eastern city, who has a reputation as a specialist in lung diseases, once told me that every patient with tuberculosis should buy a horse as soon as he came to the Southwest, remarking that there is a peculiar magnetism transmitted to the rider from the horse which greatly aids his recovery. I have looked for this magnetism in vain, nor has it been evident to any of my friends. I say without reservation that the majority of persons with tuberculosis who ride horses in this region shortly after their arrival do themselves great harm. This is especially true of persons with pleurisy.

Exercise, like all other forms of treatment, should be taken only on the advice of a competent physician.

There is a lack of proper diversion in this region. Theatrical performances are not very common, and musical entertainments are infrequent. In this respect conditions are improving. In the days when gambling was wide open (now happily passing) many who could not endure the monotony resorted to the barrooms and playhouses, and, besides losing their money, lost their health by remaining in a vitiated atmosphere and indulging in alcohol.

Work and Means of Support.—Do not send your patients to Arizona unless they have sufficient funds to cover their expenses for a year, or unless they have assured a position that will support them. There is little work such as persons with tuberculosis are able to do, and for every place there are many applicants. There is plenty of hard work for strong men in the mines and on the railroads, but few consumptives are able to undertake such work. After a residence of a year or so one's health may be so far restored as to enable him to engage in hard work. Many of the most successful business men in the territory were invalids when they arrived.

What Class of Cases Shall be Sent to Arizona?—Incipient cases do best, and the sooner they come under the influence of this climate the better. Do not delay until the diagnosis has been confirmed by finding the bacilli in the sputa, but as soon as there is a well-grounded suspicion of the disease send them out, provided they can afford it. Such patients nearly always recover. A certain proportion of those who come under the influence of this climate later in the disease also recover. When there is secondary infection, or a mixed infection, the prognosis is not so favorable. Although there have been some very encouraging reports of such cases during the past year, I do not think it advisable to send them to this region. They generally are too far gone to be benefited, and they are better left at home among their friends.

There is an impression that laryngeal cases do not do well here. My experience leads me to believe that it is well founded. The dryness of the air and the occasional dust storms tend to cause irritation of the laryngeal and nasal tissues, and all the cases of simple laryngitis that have come under my observation have done badly. It is therefore suggested that such cases be sent to a more moist climate.

Organic heart disease is usually said to do badly

in an elevated region, but Babcock does not hold that opinion, and I have known of three patients with advanced valvular disease who have improved very much since coming to Fort Huachuca, which has an elevation of about five thousand feet.

Where Shall the Patient be Sent?—To many Arizona is the "country God forgot," and is nothing but the dreary desert seen from the windows of the transcontinental trains. Others think it has an ideal climate for the treatment of tuberculosis. Neither of these opinions is correct. There are periods when the climate is anything but mild and sunny. In a previous paper* it has been shown that the Indians who live in the open air in this region are rapidly being exterminated by tuberculosis. Much of the territory is arid, but there are large areas of forests and many fertile valleys.

The health resorts may be classified as follows:

Summer stations: Flagstaff and vicinity.

All-the-year-round stations: Prescott and other points in the southern portion that have an elevation of about five thousand feet.

Winter stations: Tucson, Phœnix, and Yuma.

Flagstaff has an elevation of seven thousand feet and is situated on a mesa at the southern base of the San Francisco Mountain Range. The summer climate is delightful, the days are never hot, and the nights are always cool. Frosts occur during every month excepting July and August. The accommodations are very poor. Cottages can be had at reasonable rates, but during the summer the demand is greater than the supply. The cost of living is very high. There are two hotels, the proprietors of which profess not to take "consumptives," but there were at the time of my visit at least two stopping at one of them. The surrounding country is full of interesting ruins, and the green pine trees, with their fragrance, are very welcome to those who have wintered in southern Arizona.

Prescott has an elevation of 5,260 feet. During the summer there are some warm days, but being in the mountains there is always a breeze at night, and during the hotter hours of the day there is usually a strong wind which prevents the heat from becoming oppressive. The winter nights are cold, and those who sleep outdoors will have to be warmly clad. The humidity is low. The precipitation amounts to 15.6 inches. During the winter there is considerable snow. There are during the year an average of 228 clear days, 101 partly cloudy days, and 36 cloudy days. It is a pretty little town, and has a pleasant society. There is a hospital in the town, and about a mile west of the plaza Dr. Flinn has established a tent and cottage sanitorium. The hotels are not very good, but there are said to be some good boarding houses. Persons in the early stages will be able to find suitable accommodations, but when the disease is more advanced it will be more difficult.

Tucson has an elevation of 2,368 feet. It is distinctly a desert town, and all of its food supply is imported, consequently the cost of living is high. There are a number of pretty good hotels and several cottages that take roomers. Tents and small cottages can be rented at reasonable rates, and board can be had at any of the hotels. The climate is cooler than either Yuma or Phœnix, especially the winter nights. The mean minimum temperature for December is 37° F., and in January it is 35°. Nevertheless, many persons sleep in tents or the open air during the entire winter. There are occasional snow storms. The winter precipitation is 4.2 inches. The humidity is about the same as at Yuma and Phœnix. From October to March there are on an average 119 clear days, 42 partly cloudy days, and 21 cloudy days.

Forty miles north of Tucson, in the Santa Catalina Mountains, at an elevation of 4,500 feet, is Oracle. It is from six to ten degrees cooler than Tucson, and there are two ranches where tents and cottages can be rented at reasonable rates.

Phœnix has an elevation of 1,087 feet, and is probably the best known resort in Arizona. Being a modern town, and distinctly a health resort, the invalid will find many comforts not obtainable in other portions of the territory. The surrounding country is highly cultivated, and much of the produce used is raised in the immediate vicinity. The alfalfa fed beef is the best I have ever tasted. The mean temperature is 70° in October, and falls to 50° in January, rising to 60° in March. The average precipitation for the six months ending with March is 4.2 inches. The humidity has a greater range than in Yuma, being 41 per cent. in October, rising to 52 per cent. in January, and falling to 38 per cent. in March. During the six cooler months there are 119 clear days, 38 partly cloudy days, and 25 cloudy days. Sleeping out is possible during the entire year. In the town are numerous boarding houses, besides a large number of hotels. Just beyond the city limits there are two cottage and tent sanatoriums, where board and a tent may be had for from $12 per week up.

Yuma is situated at the point where the Gila empties into the Colorado, and has an elevation of 141 feet. The town is small and the accommodations are limited. Recently the Yuma Heights Sanatorium has been opened and better accommodations are assured. The sanatorium is only open during the winter months. The mean temperature is 72° in October, falls to 54° in January, and is 64° in March. The humidity ranges from 44 per cent. in October to 41 per cent. in March. The total precipitation for the period from October to March inclusive is 2.1 inches. During the same period there are on an average 130 clear days, 42 partly cloudy days, and 10 cloudy days. Yuma seems to be a desirable winter station for persons who cannot stand the elevation of Phœnix or Tucson. When the irrigation project now under way is completed it will become a large farming community.

In the above I have given what appear to be some of the more important causes why patients sent to the Southwest do not recover from tuberculosis. An outline has been given of the climatic conditions of the principal stations in the territory. Those who desire more exact information are referred to the following papers dealing with local conditions: Climatology of the United States, Bulletin "Q" United States Weather Bureau, 1906. The climate of Flagstaff, *Journal of the Outdoor Life*, Vol III., pages 195-197. The winter climate of Tucson, *Boston Medical and Surgical Journal*, Vol CLV., 1906, pages 307-309. The climate of Prescott, *Canadian Lancet*, Vol XL., 1906, pages 206-210.

The object of this paper is not to discourage the sending of patients to this region, but is a plea for more care in selecting cases, and to urge upon the profession not to send persons who have not the funds with which to secure proper food and comforts.

I do not believe there is any quality of this climate which will cure tuberculosis irrespective of good food and proper care, but I do believe that when patients can secure such things they stand a better

*Tuberculosis among the Indians of Arizona and New Mexico; *New York Medical Journal*, Vol. lxxxiv, 1906, p. 981.

chance of recovering in this than in any other region of our country. If there be anything in the outdoor life, then I am right. To appreciate this, one has but to compare the conditions which obtain here with what the patient is exposed to during the winter in the East. Here the invalid can be outdoors nearly all the time, while in other sections, owing to bad weather, a large portion of the time must be passed within the house. I have a patient who has not slept in the house for over a year. His only protection is a porch and a canvas screen to keep off the snow and rain.

The greatest need, from a tuberculosis point of view, is a large sanatorium conducted on the same principle as the Adirondack Cottage Sanatorium. The Federal Government has given millions of acres of the public domain for educational purposes; why should it not devote some of its desert lands to be used for those sick with tuberculosis? There is plenty of land available for this purpose. Not far from where I write is an abandoned military reservation that would answer admirably. Adjoining it is a large forest reserve which would be an excellent recreation ground for those who are convalescent.

THE STOMACH TUBE IN DIAGNOSIS.

By NELLIS BARNES FOSTER, M.D.,

NEW YORK.

For some reason which is not clear there is a belief among a number of medical practitioners in this city that the use of the stomach tube in the diagnosis of gastric disease is usually of no value, or at best an aid only in exceptional instances. These men, at least in part, are in the habit of confining their attention to the acid secretion as shown in the ordinary Ewald test breakfast. If only one test meal is taken from a patient and no observations are made on the material removed other than to estimate the amounts of free and combined hydrochloric acid, then, of course, from these facts no conclusion whatever can be made. But the man who uses only a part of a method is in a poor position to condemn the whole process. If but one observation can be made on a patient, as frequently occurs, and the presence or absence of HCl is the only fact desired, the desmoid test as used by Sahli is more convenient to both physician and patient than would be a test meal. When, however, a diagnosis is desired with anything like accuracy, much more information can be gained by the use of test meals and a few simple tests applied to the material removed from the stomach.

There are three things which must be considered in diagnosis and in the treatment of abnormal gastric conditions. They may be grouped under the headings of (1) secretion; (2) motility; and (3) the presence of abnormal materials.

While we are more conservative in drawing deductions from amounts of HCl, which we find secreted in the stomach than formerly, because it is now believed that the normal range is wider than it was at one time supposed to be, yet it cannot be denied that abnormal function in the stomach is often manifested by marked variation in the secretion of HCl, and that a hypo- or hyperacidity is important to diagnosticate, since it is so useful a clue to treatment. However, I do not think that one may conclude that he has to deal with a case of hyperacidity on the evidence of a single test meal—mental states have a marked influence on gastric secretion, and the mental state of a nervous patient anticipating his first ordeal with a stomach tube cannot be described as one of equanimity. In short, the acid findings in an initial test meal are the least accurate of the data ascertainable. Some idea of the motility in the stomach is one of the easiest facts to determine, yet it is the function most frequently neglected by diagnosticians. Simply washing out the stomach in the morning before any food is taken sometimes gives ample evidence of deficient motility. It is not a unique experience to find in the sediment from such a lavage recognizable elements of each of the three meals eaten the day previously. Another method is to remove the contents of the stomach a number of hours after a moderate meal of meat, vegetables, and bread. So many causes may give rise to deficient motility besides ectasia that it is not surprising we find it so frequently. Among these causes cicatrix (we are prone to forget that ulcers are often latent), resulting in partial stenosis of the pylorus, is most frequent in my case records, next is stenosis due to tumors, both benign and malignant, and last stenosis due to adhesions between the duodenum and some other viscus, such as the gall-bladder. These adhesions produce partial stenosis by causing kinking of the duodenum.* In conditions of this nature it is useless to endeavor to make a diagnosis without resorting to the repeated use of a stomach tube. To illustrate the importance of this method of examination one case may be mentioned:

H. C., age thirty-four. Complained of vomiting and loss in weight. His past history is unimportant. For a year he has been vomiting at irregular intervals; during the last six months he has vomited almost daily. His weight has fallen from 145 pounds to 119. He has no pain, but a feeling of discomfort in his stomach region constantly. There has never been blood in the vomitus nor have his stools been black. He has consulted three physicians, the last of whom took a test meal. He was told that his stomach secreted no acid and was directed to use acid after meals.

On examination the patient showed no evidence of organic disease—morning lavage of the stomach removed considerable residue in which food material could be recognized. Ewald test meals showed no free HCl; mucus in excess, numerous bacteria, and fermation in tubes. Lavage at varying times after meals disclosed pronounced motor insufficiency, but the stomach was not dilated and its muscle tone appeared excellent.

Believing that there existed some form of benign stricture of the pylorus, operation was advised. The condition found was a scar due to a healed ulcer at the pylorus, this scar producing so marked a contraction of the pyloric opening that only a small sound could be passed through it. Finney's operation was done and an absolute cure resulted. This case is mentioned solely as an example of those instances wherein a diagnosis might be made by inspection of the stomach contents alone without resorting to any tests whatsoever. This simple inspection is too frequently omitted.

The most important abnormal material to look for in test meals is blood. The presence of occult blood in the stomach contents is quite constant in cases of carcinoma, and a frequent finding in ulcer cases. It signifies little what test is employed, the guaiac, aloin, or the various modifications of these tests are all good.†

*The cause of stenosis in these cases was either confirmed by or determined at operation.

†Where ulcer or cancer is suspected the diet should be made meat free for a couple of days, in order to permit of examination of the feces for occult blood.

These tests for blood are so simple and the results are not infrequently so important that one can ill-afford to neglect them. Blood is found in other conditions than ulcer and carcinoma, *i.e.* esophageal varices, erosions of the mucous membrane, but a differential diagnosis is seldom difficult and the existence of the mentioned possible origin of blood does not detract from the value of the test when used as a routine in gastric analysis.

Of more questionable worth is the microscopic examination of smears of the gastric contents for bacteria. Occasionally such large numbers of microorganisms are found that a clue is given to the nature of the disorder, and the finding of Boas-Oppler bacilli or sarcinæ is significant. In the majority of examinations so few bacteria are present that a fermentation test of the gastric contents in fermentation tubes is, perhaps, a more trustworthy guide to the nature of the bacteria present. The omission of the microscopic examination, however, is inadvisable.

There exists an impression, which has been shown repeatedly to be false, that the presence of free hydrochloric acid in the stomach excludes the formation of lactic acid. It is quite possible for lactic acid fermentation to proceed in the presence of HCl, and the former should always be looked for in routine analysis; especially is this true in connection with the early recognition of carcinoma, since the early differentiation of this malady is the only hope of successful surgical aid.

The interpretation of facts disclosed by the employment of test meals is not always clear, but error lies more often in drawing a conclusion from insufficient data than it does in misinterpretation. The presence of a normal amount of free hydrochloric acid in the gastric secretion is not incompatible with carcinoma, nor does the absence of free acid of necessity indicate this malady. Other data, such as the presence or absence of occult blood, lactic acid, etc., are indispensable. But in no other way can one detect cancer of the stomach at a sufficiently early period to make an operation of therapeutic use. When a tumor has developed so that it may be felt, the time for complete removal of the growth has gone by. In the benign gastric conditions, stenosis of the pylorus and marked dilatation wherein surgical aid is being found so useful, the stomach tube is the quickest means and most reliable for determining when such aid shall be considered. The differentiation of gastric ulcer from gastric neuroses can hardly be made with any degree of confidence without recourse to test meals.

In conclusion it must be especially emphasized that the determinations of the acidity of the gastric juice are the least dependable of the diagnostic data, and that when this alone is done valuable aids, such as the tests above mentioned, are ignored.

The tests I have mentioned are those which have been most fruitful in my experience in securing diagnostic data. I am convinced that anyone using these methods with care will find them constantly a help and often indispensable to diagnosis. The surprising thing is that after the advances that have been made in the diagnosis of gastric disorders, particularly cancer and ulcer, any one should feel in doubt about the utility of the special method on which these advances primarily depend.

A Titled Ophthalmologist.—The Emperor of Austria has conferred on Duke Karl Theodor of Bavaria the Order for Art and Science in recognition of his distinction as an ophthalmologist.

OPERATION FOR INTESTINAL OBSTRUCTION IN A CHILD OF FIFTY-FIVE HOURS—DEATH IN SEVENTEEN HOURS.

By HOWARD CRUTCHER, M.D.,

MEXICO, MO.

In the early hours of January 8, 1907, I was called by Dr. M. E. Crawford of this city to see with him a female child that had passed nothing from its bowels since birth. The child appeared to be perfectly developed and very vigorous, but presented a clear-cut picture of total intestinal obstruction. Dr. Crawford had tried mild purgatives without effect, and together we applied water pressure through the rectum without good results. There were occasional vomiting spells and the distention was extreme. The case presented an almost hopeless outlook, but Dr. Paul E. Coil, who had been summoned in the meantime, agreed with Dr. Crawford and myself that the child was justly entitled to the only possible chance to save its life. With this conclusion the parents of the child agreed, not, however, without receiving the usual flood of feminine lay advice, which is always most vigorous and voluminous when backed by the densest ignorance.

No anesthetic was given. Through a small incision in the right inguinal region the exploring finger detected a collapsed colon and a highly distended small intestine. Peritonitis was already well advanced. A loop of ileum was drawn into the wound and a fecal fistula established by the usual methods. The bowel was opened at once, and a profuse discharge of gas and fecal matter followed. This continued at intervals during the remaining hours of life.

The child ceased to vomit, retained some slight nourishment, grew more quiet, but gradually sank, and died seventeen hours after the operation, apparently from extension of the peritonitis. The infection started no doubt from the point of occlusion and traveled through the intestinal wall.

I regret that I am unable to throw any more light upon the cause and seat of the obstruction in this case. A prolonged or extensive operation would have killed the patient on the table. We did the only practicable thing and lost. Unfortunately no post-mortem examination was permitted. The case is reported only on account of the tender age of the patient. I believe that every such patient should be given the benefits of surgery, without regard to the dark outlook ahead. Without the blessings of modern teaching and practice the outlook would be much darker than it is.

Why Defective Nasal Respiration Impedes Growth and Development.—P. Watson Williams declares that the pernicious effects of mouth-breathing in children are seen in the constant tendency to infective catarrhs, bronchial colds, and pulmonary complaints, from which children with adenoids and some other causes of nasal obstruction are prone to suffer. "Adenoid growths" are by far the commonest cause of defective nasal respiration in childhood. The absence of normal nasal respiration causes pulmonary troubles and defective development of the chest wall. It may be said that children who persistently fail to expand their lungs are underfed. After abnormal conditions in the nose and throat are removed the physician should advocate the advantage of open air, cold bathing, and appropriate respiratory exercises, in order that these listless, partly asphyxiated children may grow up in the fullness of life.—*The Bristol Medico-Chirurgical Journal.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, April 20, 1907.

THE RELATION OF IMMIGRATION TO THE PREVALENCE OF INSANITY.

THE constant increase in our asylum population cannot serve otherwise than as an indication that mental disease is on the increase. The question naturally arises to what is this due, and the answer is that it may be traced to several sources. One of these was discussed at the recent New York State Conference of Charities and Correction following a paper by Dr. T. W. Salmon, who is in charge of the medical inspection service at the immigrant station on Ellis Island. In addition to the cases of insanity which originate among what we may for practical purposes designate as the native population, there is a large influx to this class from among our immigrants. New York being the chief port of entry, it is natural that it should become the destination of those immigrants of defective physical and mental equipment whose means do not suffice to carry them further. This tendency to remain is fostered by the large colonies of aliens in this city which assure some support to a dependent countryman. It is also a matter of statistics that, although this State receives but thirty-one per cent. of the entire immigration into the United States, it is the intended destination of more than seventy per cent. of those who are admitted to the hospitals upon their arrival at Ellis Island, certified as being unfit to land on account of some mental or physical defect.

That a definite relation exists between these figures and the prevalence of insanity in this State is a conclusion which is made very evident by Dr. Salmon in his thoughtful paper. In 1875 the ratio of the insane to the whole population was one in 675; in 1895 it was one in 294. In order to arrive at some opinion as to the part that immigration has played in this result, it is necessary to consider a number of questions. First among these is the proportion of foreigners in our institutions for the insane. The reports of these hospitals show that in 1905 one in 190 of the foreign born and one in 363 of the native population was in an institution for the insane. Of all the admissions to the New York State hospitals since 1888, 48.4 per cent. were of foreign birth, although the foreign born never exceeded 26 per cent. of the entire population of the State. It would appear only reasonable to suppose that the immigration in recent years especially has contributed very heavily and quite disproportionately to the prevalence of insanity in this State.

Within the past decade the type of immigrant has changed considerably, and where we once had a preponderance of the northern races of Europe, we now find the Hebrew, Slav, and Italian more strongly represented. An attempt to compare the ratios of insanity between the "old" and the "new" immigration is scarcely practicable with the data at hand, although it is quite generally admitted that among the Hebrews certain types of mental disease are very prevalent. Whatever doubt there may be, however, about the relative occurrence of insanity between these two classes, there is no such uncertainty about the proportion of idiots and other mental defectives. Defectives are as great a danger to the community as the insane, for especially those of the lighter types are not admitted to institutions for the insane, but are at liberty to exercise at large their criminal instincts and deformed moral sense. This makes them not only undesirable members of society, but frequently public burdens in the penal institutions. It appears from the record that many defectives are landed at Ellis Island, but unfortunately the present immigration law does not make their deportation mandatory unless they are actually in a condition of idiocy. The fact is that during the past year 15 per cent. of those certified for imbecility or other mental defects were admitted to this country by the authorities.

There are laws to prevent the landing of the insane or to provide for deportation if they become a public charge within two years after admission. It seems, however, that there are numerous loopholes through which escape is possible. It may be difficult to subject these errors to direct reform, but there are other ways in which some good can be accomplished in preventing the entrance into this country of undesirable individuals of this type. Insanity is apparently sufficiently dealt with in the immigration laws, but the latter should be amended to include in the prohibited class all mental defectives and those certified as having evidences of constitutional mental inferiority or instability. With a law of this kind all those undesirable accessions to our population which are likely to develop criminal tendencies could also be excluded. We are undoubtedly confronted by a serious problem as regards the character of some of our foreign-born population, and the question should be regarded in a sensible light rather than in the sentimental aspect which finds favor among a certain class of our population. We need the immigration, but it must be selected, and the selection should be based on mental and bodily fitness rather than on other and less important considerations.

THE COLLEGE OF PHYSICIANS AND SURGEONS.

THE *Columbia University Quarterly*, in giving up practically the whole of its current issue to articles on subjects concerning the medical profession, bears graceful witness to the prominent position of the medical faculty in the fabric of the University. The number commemorates the centenary of the old College of Physicians and Surgeons, now the Medical School of Columbia University, which received its charter on March 12, 1807, and in November of the same year opened its doors in a house on Robinson street, now Park place. Six years later the new

institution absorbed the already languishing medical school of Columbia College, in 1860 entered into a nominal union with Columbia College, and in 1891 became an integral part of the University, thus realizing what is said to have been a cherished dream of the eminent Dr. Samuel Bard, under whose early presidency the foundations of the institution's future prosperity were laid.

The record of the institution's development from its modest beginning with a faculty of seven members and a first graduating class of eight, to its present importance, is traced in engaging fashion by Dr. Frederic S. Lee, while an interesting side light on the medical life of the city a century and more ago is afforded by a sketch of the life of Dr. Bard contributed by Dr. Walter B. James. Dr. M. Allen Starr, in an article on medical education in New York, rehearses the manifold advantages of this city as a center for medical education and the opportunities for undergraduate and advanced workers offered by its seventy-four hospitals and fifty-three dispensaries—to leave out of the count Brooklyn's large list of medical institutions. The teaching anatomical museum for undergraduates, a recently elaborated feature of the equipment of the school, is described by Dr. George S. Huntington, and Dr. James A. Miller outlines the progress of the antituberculosis movement in New York.

The address entitled "Medical Ideals and Medical Tendencies," delivered by Dr. L. Emmett Holt at the opening of the college last fall, is reproduced, and forms a delightful essay on the attitude of the physician to his life work, well worthy of the consideration of every medical reader. In pointing out the undesirability of a too blind subservience to what he terms the scientific spirit in modern medicine, which tends to sacrifice to some extent the faculty of careful bedside observation to the cult of laboratory diagnosis, Dr. Holt touches on one of the difficult problems of modern medical instruction, which is discussed at length by Dr. Francis C. Wood in an article on the department of clinical pathology of the college. In this thoughtful paper the necessity for a broader policy of coordination between hospital laboratory and hospital ward is indicated, and a well-rounded system of undergraduate and postgraduate instruction in clinical pathology, which shall be abreast of modern conditions and yet free from one-sidedness from either the laboratory or the clinical standpoint, is convincingly advocated. In the editorial department are to be found pertinent comments on the anniversary celebration of the College of Physicians and Surgeons which is to be held in June, and on the quiz system and the clinic in medical teaching.

This commemorative number of the *University Quarterly* serves but as one more illustration of the mutual benefits that have attended the coalition of the two institutions, and of the fact that the art of medical pedagogics has been much advanced by their union.

METALLIC SUTURES.

The general popularity of the absorbable suture has led to the practical abandonment of most other materials for this purpose, particularly when they are to be buried in the tissues. The absorbable suture, however, has always the uncertainty connected with it of becoming the center of growth for an infectious process or of continuing the same when placed in its close proximity. The truth of this has been recognized in the attempts which have been made to impregnate catgut, for example, with iodine and other antiseptic agents. Certain of the metals are known to possess the property of inhibiting the growth of microorganisms, but sutures of these materials seem to have found little favor except in isolated instances. The main objection to them has been the local irritation which they are said to cause, but it has often been shown that this need not interfere with their employment.

The antiseptic value of the metal suture has again been studied by Leedham-Greene (*The Practitioner*, March, 1907), who examined the inhibitory properties of a number of metals when incubated with gelatin or agar cultures of staphylococcus aureus. In the case of the majority of the metals, the presence of the wire loop in the gelatin seemed to have little or no influence on the growth of the microorganisms, which flourished in all parts of the dish, as well as in the immediate vicinity of the metal. But it was evident that some metals exhibited a distinct and powerful inhibitory action upon the bacterial growth. In these cases the culture medium in the immediate neighborhood remained free from growth, a microscopical examination of the plates confirming the gross appearance. Gold, platinum, tin, aluminum, magnesium, and nickel showed practically no inhibitive power, and lead and silver only when cultures grown at a low temperature were employed. Iron exhibited a variable action, depending on whether oxidation was hindered or favored.

From the bactericidal standpoint, copper proved the most powerful of the metals, and, in a less degree, its alloys, bronze and brass. It would appear that a metal possessing this power of inhibiting bacterial growth to a marked degree would prove suitable for suture material providing its ductility, tenacity, and freedom from irritating properties were not affected. Silver, although apparently the most widely used, does not conform to these specifications to any marked degree; it is costly, not as tough or ductile as might be desirable, and its antiseptic power is insignificant. Aluminum-bronze wire has been largely used on the Continent to supplant silver, and from the large amount of copper present (95 per cent.), it would be likely to meet the desired indications. The metal, being rather soft, cannot be used in the form of screws or nails, and Leedham-Greene suggests a true bronze, consisting of a mixture of copper and tin, for this purpose. It has been shown that sutures of this kind which possess a certain degree of bactericidal action are less irritating to the tissues and less apt to be followed by the production of sinuses than those having no antiseptic value. Pure copper would seem to be the most nearly ideal material for the purpose, and, although it is generally considered to be too irritating to the tissues, Greene finds that in his own experience this assumption is not borne out by the facts. While absorbable sutures will probably continue to be preferred for routine use, it is possible that Greene's suggestions may prove practicable for certain cases.

CLOTHING FOR THE TROPICS.

In his interesting work on "The Influence of Tropical Light on White Men," Major Charles E. Woodruff speaks of the mistaken notion that white is the best color for clothing in the Tropics. It is true that white garments reflect the heat rays, but the actinic rays pass through them readily; hence if they are worn it should be in conjunction with yellow, red, or black underclothing. The negro with a white suit is, he says, the most contented of beings under a tropical sun, and the white man should imitate him, supplying the missing pigment by black undergarments.

Dr. Louis W. Sambon, writing in *The Journal of Tropical Medicine and Hygiene* for February 15, 1907, on the subject of tropical clothing, comes to the same conclusion. "The use of white clothing for the Tropics," he says, "has been adopted in imitation of native custom, and no doubt it is wise to follow the dictates of a long experience; but those who borrowed this custom overlooked the all-important fact that the native is already fully protected by a natural armor of pigment which is impervious to the harmful actinic rays. Having no reason to fear the chemical rays of the sun, the native dons an ample white robe, which, by reflecting the long heat rays, keeps him comfortably cool." But even the natives do not always wear white, for red, yellow, and brown are really the predominating colors, more especially with regard to the protection of the head and abdomen. White is for comfort, but health demands a lining of pigment.

To avoid the additional weight and thickness of several layers of cloth, Dr. Sambon conceived the idea of a fabric composed of white and colored threads, woven in such a way as to produce a warp or outer surface of white and a woof or inner surface of black, red, or orange. For army use, where a white tunic would be undesirable, he used threads of yellow and blue for the warp and red for the woof, producing a khaki effect externally with a red color-screen for the inner surface. Such a cloth, with a heat-reflecting outer surface and an opaque inner layer, will, he thinks, meet all the requirements of comfort and protection for garments for tropical use.

THE CLINICAL THERMOMETER.

In view of the immense number of thermometric determinations that are being made in medical practice, and of the important deductions drawn from them, the subjects of the accuracy of the instruments employed and of the physiological variations in body temperature certainly deserve more attention than is usually accorded them. Most practitioners probably take it for granted that the thermometers—at least those of the medium and better grades—supplied by the dealers are instruments of precision, yet comparison with a standard thermometer will often reveal a most astonishing degree of inaccuracy. While the fragile nature of the instrument and the vicissitudes of daily use usually preclude any serious inaccuracy due to the changes attending the so-called seasoning of the glass, if a thermometer survives more than a year it should be retested and the necessary corrections noted. Very little consideration also is usually given to the subject of the normal fluctuations of temperature, which are much wider than is commonly realized. In this connection Myers (*Yale Medical Journal*, April, 1907) says that the temperature of the healthy human body undergoes certain variations which, when graphically expressed, take the form of a curve, the essential characteristics of which are an evening fall, with a minimum somewhere between 12 midnight and 6 A.M., and a marked rise in the morning with a maximum between 4 and 6 P.M. The temperature in the course of twenty-four hours may vary through a range of 2° C. (3.6° F.) under perfectly normal conditions. Thus, in observing the late afternoon or early evening temperature, a record might be obtained as high as 38° C. (100.4° F.), or again, the temperature in the early morning might be as low as 36° C. (96.8° F.) under normal conditions. After any muscular exertion, such as a rapid walk to the physician's office, one might expect to observe a temperature as high as 37.5° C. (99.5° F.) in a normal individual. A point which should be much emphasized lies here. Unless a distinctly febrile temperature is observed, there are many factors which must be considered in using body temperature as diagnostic of an abnormal condition. It appears that each person has his own normal body temperature and normal curve of fluctuation, and these must always be taken into consideration if possible in clinical temperature determinations. While the causes of the fluctuations in normal body temperature are incompletely understood, it is known that muscular work, food, and the standing position elevate the body temperature, while inactivity, rest, and possibly fasting, have the reverse effect.

TO PREVENT PREMATURE BURIAL.

The problem of discovering a simple yet reliable sign of death is one that has attracted much interest in France, and several prizes have been offered for its solution. One of these was some years ago awarded to Dr. Icard of Marseilles, who has been a prolific experimenter and writer on the subject, and has even succeeded in inducing the municipal authorities of several cities to give their official sanction to the use of his fluoresceine test. This consists in the subcutaneous injection of a solution of fluoresceine; if circulation of the blood, however sluggish, is still going on, the skin in the course of a few hours becomes intensely yellow and the conjunctiva green. This discoloration is only temporary in the living, and the procedure is not injurious. A somewhat simpler, though perhaps equally dramatic test, is one that he has lately suggested. It is founded on the blackening produced in solutions of lead acetate on contact with sulphuretted hydrogen, and is carried out by writing a few words such as "I am dead" with a solution of the lead salt on a strip of paper. This apparently blank slip is to be rolled up and placed in the nostril of the supposed corpse. It is alleged that before any external evidences of putrefaction can be detected sulphuretted hydrogen is given off from the lungs, and the writing, therefore, becomes visible if death has taken place. Icard proposes that such slips of paper be given to persons reporting deaths at which no physician has been present, with the direction to place them in the nostrils of the deceased. The next day the slips are to be brought back to the proper official, after the dead person has, so to speak, made out his own death certificate. The conception is certainly ingenious and has an attractive touch of the theatrical, but unfortunately doubts have been cast on its reliability. At least the *Edinburgh Medical Journal*

states that in many cases in which the test was applied it failed to give satisfactory results, and in bodies that had been kept for a week or more, and in which other evidences of putrefaction had long appeared, the pieces of lead paper in the nostrils did not show more than the merest trace of discoloration.

Orthostatic Albuminuria.

In connection with Heubner's recently reported case of orthostatic albuminuria with autopsy (Medical Record, February 2, 1907), it is interesting to note a communication of Langstein's in the *Berliner klinische Wochenschrift*, January 28, 1907, referring to the nature of the albuminous bodies to be found in the urine in instances of this peculiar affection. Langstein has found that in all specimens of albuminous urine from patients with orthostatic albuminuria an albuminous body which is precipitated by acetic acid is present. Those cases in which only this body is found are *per se* to be distinguished from cases of chronic nephritis, whereas in the chronic nephritis of children this particular albuminous body is either absent or is present in smaller amounts than the ordinary albumin. For its detection he suggests the following mode of procedure: Two test tubes are filled to the same height with urine, a few drops of dilute acetic acid are added to each, and the tubes are shaken for several minutes. The specimens are then diluted with three or four volumes of water, and to one of them a few drops of potassium ferrocyanide solution are added. On holding the tubes against a black background the presence or absence of the acetic acid albumin in the one tube can be determined and its bulk may be compared with that of the total albumin in the other. The addition of water after acidulating is necessary in order to prevent the precipitation of uric acid from a urine of high specific gravity. The nature of this albuminous body is still uncertain, but it appears to resemble that which von Leube discovered in about two-thirds of a large number of healthy soldiers after moderate exertion.

The Breast Feeding of Infants.

In spite of the efforts of pediatrists to popularize a knowledge of the advantages of breast feeding, there seems to be little doubt that the practice of artificial feeding is becoming more prevalent, instead of the reverse. It is usually assumed that resort to bottle feeding as a matter of mere expediency is a problem to be dealt with primarily among the better classes, but Neumann (*Deutsche medizinische Wochenschrift*, February 21, 1907) shows that in Germany, at least, the tendency is growing among the poorer people as well. He estimates that artificial feeding of infants has increased by about two-thirds in Berlin since 1885 in all classes of the population. In that year, among the families inhabiting one or two rooms, 70 per cent. to 80 per cent. of the mothers could have nursed their infants, and 65 per cent. actually did so. Now, however, about 50 per cent. resort to bottle feeding without sufficient reason, and among the families living in four or more rooms, in 1900 only 30 per cent. of the mothers were found nursing their infants. It is not necessary to rehearse Neumann's list of the reasons that make natural feeding preferable to artificial—they are sufficiently well known to medical men—but the Berlin statistics, even if not directly applicable to conditions in this country, at least should serve as an additional incentive to make every effort to encourage breast feeding.

The Cause of the Odor of Ozena.

It is quite generally acknowledged that the fetor which accompanies ozena is out of proportion to the extent of the lesion, and very little is known of the immediate causes of its production. Frese, who has recently investigated this subject (*Deutsches Archiv für klinische Medicin*, Vol. 86), finds that the odor is of a mixed origin. Chemical analysis of the secretion has shown the presence of a variety of substances which are always found in the process of decomposition of albuminous materials. Chief among these are a number of fatty acids, volatile in character, which constitute the principal offensive substances, and seem to arise from a direct conversion of the neutral fats. The secretion itself is without odor when first formed, but its peculiar constitution renders it immediately liable to decomposition in the presence of microorganisms. Frese finds, however, that the so-called ozena bacillus is unable to institute this process. It was also determined that the foul products arising from a tertiary nasal syphilis are of the same general character as those associated with true ozena.

A New Pupillary Reaction.

An interesting observation has recently been made by Löwy (*Neurologisches Zentralblatt*, 1906, No. 20), with reference to the behavior of the pupils in the presence of local painful areas. He claims that when the pupils are contracted by intense light, the pain elicited by pressure on an organically diseased region will be accompanied by a distinct relaxation of the pupillary ring, whereas that proceeding from a functional lesion is not distinguished by this phenomenon. Löwy believes that this symptom is of value as a differential diagnostic sign in avoiding a confusion between pain of an organic and that of a psychic origin, such as is associated with hysteria. Likewise in traumatic neuroses it may serve to show whether the tenderness elicited at the site of the injury is due to the trauma itself or is of psychic origin.

News of the Week.

A Chair of Hydrotherapy.—Dr. Simon Baruch has been made Professor of Hydrotherapy in the medical department of Columbia University, and a hydrotherapeutic department is to be established in the Vanderbilt Clinic. In this department students in small sections will receive practical instruction in hydrotherapy, the course being an obligatory one, and the final examinations will include this subject. It is not necessary to point out what a valuable innovation this will be.

Iroquois Memorial Hospital in Chicago.—The project recently submitted to the County Board for the establishment somewhere downtown of an institution to be known by this name was recently unanimously indorsed by the Council of the Chicago Medical Society. Dr. George W. Webster, President of the Chicago Medical Society, supported the resolution of indorsement and spoke in favor of its adoption. In return for the use of its name, the Iroquois

Memorial Association agrees to contribute a fund of $25,000 already collected for that purpose, and such other sums as may be raised by members of the Association.

Results of Examinations for Internes.—Of ninety-six students recently examined at the Cook County Hospital, forty-four students passed the required grade for interneship. Fifteen of the successful applicants will be appointed internes in June.

Work of the Antismoke League.—This organization, acting in conjunction with the Health Department, during the last year caused 193 arrests for violations of Section 26 of the Sanitary Code which provides that no smoke, cinders, or noxious gases shall be allowed to escape from chimneys, etc. Of the persons arrested, 132 were convicted, 36 were discharged, and at the end of the year 25 cases were pending. The effect of this activity on the part of the League is shown in the record of convictions for this offense in previous years: 1902, 17 convictions; 1903, 45 convictions; 1904, none; 1905, none; 1906, 132 convictions.

Smallpox.—The Russian steamer *Petersburg*, which arrived last week from Libau and Rotterdam with 981 steerage passengers, was detained at quarantine because of a case of smallpox in the steerage. The patient, who had been ill eight days, was transferred to the Kingston Avenue Hospital, and 150 passengers who occupied the same compartment were sent to Hoffman Island for observation. The steamer was disinfected. Owing to the occurrence of nine cases of smallpox in Chelsea, Mass., three of the public schools of the city have been closed as a precautionary measure.

Yellow Fever.—In the port of Kingston, Jamaica, a rigid quarantine has been established against vessels from Cuba and Trinidad, where yellow fever has appeared.

Child Labor Bill.—The Page child labor bill was passed by the Assembly at Albany on April 9. Originally the bill provided that children could be employed between the hours of 7 A.M. and 7 P.M., but in the Assembly it was amended, and the bill passed prohibits the employment of children except between the hours of 8 A.M. and 5 P.M.

To Control Expert Testimony.—A bill has been introduced in the Assembly at Albany which is intended to restrict the scope of expert testimony in regard to the mental condition of defendants in murder trials. The bill provides that the expert must have actually examined the person concerning whose mental state he is to testify, and also provides against the abuse of the hypothetical question.

Appropriations for State Institutions.—Among bills recently signed by Governor Hughes are those providing for appropriations for State Hospitals as follows: Binghamton Hospital, $50,000 for new dining room and kitchen, $81,000 for nurses' home, and $7,500 for water supply; Middletown Hospital, $81,000 for nurses' home; Hudson River Hospital, $81,000 for nurses' home; Kings Park Hospital, $62,000 for new laundry.

New Home for Incurables.—Mrs. Henrietta M. Parker of this city has filed the plans for the erection of the Parker Home for Incurables, at Eastern avenue and Landing road, New Brunswick, N. J., which she intends to build in memory of her husband, the late Francis Parker of this city. The building will have a basement, two hospital wards, and thirty-one rooms, which will include sun parlors, offices, nurses' rooms, baths, living rooms, etc. The building will be of brick and marble and will command a magnificent view of the Raritan and surrounding country. It is expected that it will be ready for use November 1.

Professor William Keen of Philadelphia, a delegate to the German Surgical Congress in Berlin, has been elected an honorary member of the German Surgical Society, and was one of five delegates received at a special audience by the German Empress.

Dr. P. F. Chambers has been appointed Clinical Professor of Gynecology in the medical department of Columbia University.

An International Congress of Psychiatry, Neurology, Psychology, and the Care of the Insane is to be held in Amsterdam on September 2 to 7, 1907. It will differ from the preceding congresses that have been held in Brussels, Paris, Antwerp, and Milan, in having a section of experimental psychology.

International Medical Association for the Suppression of War.—Dr. J. Rivière, 25 Rue des Mathurins, Opèra, Paris, the president of this society, invites correspondence from those interested in the subject relative to an international congress of physicians to be held in Paris during the year 1908.

Exhibit of Colored Physicians at Jamestown.—In order to demonstrate the progress of the negro race in medical education, an emergency hospital, under the direction of colored physicians and attended by colored nurses, is to form part of the negro exhibit at the Jamestown Exposition. The hospital building will include an exhibition room, in which a display of hospital records and supplies, pathological and bacteriological specimens, etc., will be shown. The following committee is in charge of the medical exhibit: Dr. A. M. Curtis, Washington, D. C.; Dr. George C. Hall, Chicago, Ill.; Dr. R. F. Boyd, Nashville, Tenn.; Dr. W. A. Warfield, Washington, D. C., and Dr. Joseph J. France, Portsmouth, Va.

Springfield (Mass.) Academy of Medicine.—This organization received its charter on April 9, and was formally inaugurated. Officers were elected as follows: *President*, Dr. W. A. Smith of Springfield; *First Vice-President*, Dr. John A. Houston of Northampton; *Second Vice-President*, Dr. R. H. Seelye; *Secretary*, Dr. Joel I. Butler; *Treasurer*, Dr. H. W. Van Allen. There are already more than 200 names on the charter list, representing Vermont, New Hampshire, and Western Massachusetts as far east as Worcester, and the list will be left open for the next thirty days. It is planned ultimately to erect a building for the academy, with assembly hall, library, etc.

Dr. J. William White, John Rhea Barton Professor of Surgery in the University of Pennsylvania, and Senior Surgeon to the University Hospital, has been appointed advisory surgeon to the Pennsylvania Railroad Company.

Transfer of Insane Patients.—In consequence of a fire in one of the buildings of the State Hospital for the Insane at Norristown, Pa., one hundred male patients have been transferred temporarily to the Insane Department of the Philadelphia Hospital. Plans are already under consideration for the reconstruction of the burned building, or it may be decided to utilize a sum of $416,000 appropriated by the present Legislature for the purpose of erecting an entirely new series of buildings.

For the Suppression of Cerebrospinal Meningitis.—In an effort to prevent the further spread of cerebrospinal meningitis, a number of cases of which have recently been observed in the city of

Philadelphia, Dr. A. C. Abbott, Chief of the Health Bureau, has ordered a house-to-house inspection in the lower wards of the city. In addition, the co-operation of the Department of Public Works will be asked for the purpose of making a thorough and careful inspection of the streets and alleys in the section named.

Bloodshed in Italy.—Recently published statistics show that in Italy there has been a decrease in the number of persons killed by violence, which is attributed mainly to the progress of surgery, however, for there has been an increase in the number of wounded. During the year 1903, 3,106 persons were murdered and 93,768 wounded, and it is calculated that in a period of twenty-seven years 97,000 persons met violent deaths and 2,000,000 have been wounded. The record for criminality is held by Sicily, where the proportion of murders reaches 42 to every 100,000 inhabitants in the province of Girgenti. The proportion decreases in other provinces and falls to 25 for every 100,000 in Naples. It still further decreases considerably in northern Italy, where, at Bergamo, there is only one murder for every 100,000 persons.

Women's Medical Society of New York State.—An organization having this title was formed in Rochester on March 11. On the occasion of the seventy-eighth birthday of Dr. Sarah R. Adamson Dolley of Rochester, the Blackwell Medical Society of Rochester, The Physicians' League of Buffalo, The Women's Medical Association of New York City, and The Dr. Cordelia A. Greene Society of Castile, affiliated and invited the women physicians of the State to join them at a banquet, the new society being then organized. The officers are as follows: *Honorary President*, Dr. Elizabeth Blackwell of Hastings, England; *President*, Dr. Sarah R. Adamson Dolley of Rochester, N. Y.; *First Vice-President*, Dr. Electa B. Whipple of Buffalo, N. Y.; *Second Vice-President*, Dr. Mary H. Cotton of New York City; *Third Vice-President*, Dr. Mary Theresa Greene of Castile, N. Y.; *Secretary*, Dr. Eveline P. Ballintine of Rochester, N. Y.; *Treasurer*, Dr. M. May Allen of Rochester, N. Y.

Northern Medical Association, Philadelphia.—At the annual dinner held April 10, toasts were responded to as follows: "The Anamolies and Curiosities of Medicine," by Dr. Walter L. Pyle; "Medical Legislation," by Dr. Henry Beates; "Modern Surgery," by Dr. John B. Deaver; "The Ladies," by Dr. Charles P. Noble, and "Some Reminiscences of Philadelphia's Medical Teachers and Practitioners," by Dr. Chas. K. Mills.

Officers of Tennessee State Medical Association.—At the seventy-fourth annual session of this Association held at Nashville, April 9, 10, and 11, the following officers were elected for the ensuing year: *President*, Dr. A. B. Cooke of Nashville; *Vice-Presidents*, Dr. R. E. Fort of Nashville, Dr. Chas. P. McNabb of Knoxville, Dr. R. W. Tate of Bolivar; *Secretary*, Dr. Geo. H. Price of Nashville, reelected; *Treasurer*, Dr. W. C. Bilbro of Murfreesboro, reelected; *Delegate to the American Medical Association*, Dr. S. W. Woodyard, Greenville; *Alternate Delegate*, Dr. C. E. Ristine, Knoxville. Knoxville was selected as the place for holding the next annual session.

Asotin County (Wash.) Medical Association.—At a meeting of this organization held in Clarkston on April 1, officers were elected as follows: *President*, Dr. L. W. Woodruff of Asotin; *Vice-President*, Dr. P. W. Johnson of Clarkston; *Secretary*, Dr. I. U. Temple of Clarkston; *Treasurer*, Dr. S. D. Brazeau of Asotin.

Association of Railway Surgeons.—The surgeons of the T. P. and W. Railway met in Peoria, Ill., on April 1 and formed a society to be known as the T. P. and W. Railway Surgeons' Association.

Davidson County (N. H.) Medical Society.—Officers were elected as follows at the meeting of this society held on April 2 in Newmarket: *President*, Dr. Marvin M. Cullom; *Vice-President*, Dr. Rufus E. Fort; *Secretary and Treasurer*, Dr. Holland M. Tigert, reelected.

New London County (Conn.) Medical Society.—At the annual meeting of this society held in New London on April 4, officers were elected as follows: *President*, Dr. Harry M. Lee of New London; *Vice-President*, Dr. M. E. Fox of Montville; *Clerk*, Dr. E. C. Chipman of New London.

Garland County (Ark.) Medical Society.—At the recent meeting of this society, officers were elected as follows: *President*, Dr. O. H. Burton; *Vice-President*, Dr. F. H. Tribble; *Secretary*, Dr. M. F. Mount; *Treasurer*, Dr. J. S. Horner.

Hartford County (Conn.) Medical Society.—The one hundred and fifteenth annual meeting of this society was held in Hartford on April 2. The following were elected as officers for the ensuing year: *President*, Dr. Edward K. Root of Hartford; *Vice-President*, Dr. Charles M. Wooster of Tariffville; *Secretary*, Dr. Frederick B. Willard of Hartford.

In Honor of Dr. Hodgen.—Under the auspices of the St. Louis Medical Society memorial exercises will be held in that city on April 28, in commemoration of the twenty-fifth anniversary of the death of Dr. John T. Hodgen. A generation ago Dr. Hodgen was one of the prominent figures in American medical life, and he served at different times as president of the American Medical Association, the Missouri State Medical Society, and the St. Louis Medical Society.

In Memory of Möbius.—A committee of German physicians, of which Dr. Curt Rheinhardt of Leipzig is the secretary, has been organized for the purpose of collecting a fund to be used to establish a yearly prize to be given as a memorial to the late Dr. Paul J. Möbius of Leipzig. It is planned alternately in one year to award the prize for an original paper to be published in the *Psychiatrisch-Neurologische Wochenschrift*, and in the next for the best article on a psychiatric or neurological subject to have been published in the two preceding years.

Obituary Notes.—Dr. Dicia H. Baker of Birmingham, Ala., died on April 4, at the age of forty-four years. She was a native of Tennessee and was graduated from the Laura Memorial College of Cincinnati. Dr. Baker was the first woman to be graduated in Pharmacy from the Vanderbilt University at Nashville. She had practised in Birmingham about eight years.

Dr. A. F. Ritchie of Duluth, Minn., died on April 1 at Mt. Clemens. He was born in 1854, and was graduated from McGill University in 1876. After several years of post-graduate work in Europe he began practice in Duluth, where he had resided ever since.

Dr. Henry W. Spillman of Edgerton, Wis., died on April 2 at the age of eighty-seven years. For the past twenty-seven years he had practised in Edgerton.

Dr. Frank Riley of St. Joseph, Mo., died at the age of forty-eight years, of paralysis, on April 1, after several years of illness. Dr. Riley was a native of Illinois, and received his early education in the

university of that State. In 1882 he was graduated from St. Joseph Medical College, and after practising for some years in Bolckow and in Aurora he removed to St. Joseph.

Dr. CHARLES B. COMBE of Brownsville, Tex., died on March 31 at the age of seventy years. He was born in Davis County, Ky., and received his medical degree from Jefferson Medical College in Philadelphia in 1858. After a year in the Charity Hospital of New Orleans he located in Brownsville, and served during the Civil War as surgeon on the staff of General Magruder. At various times he was president of the Brownsville and Matamoras Medical Association, president of the district Medical Examination Board, and State Health Officer.

Dr. HENRY P. EVARTS of Grand Rapids, Mich., died on April 1 at the age of sixty-two years. Dr. Evarts was born in Madison, O., and was graduated from the Cincinnati Medical College in 1870. He had practised in Grand Rapids for over eighteen years.

Dr. LAWRENCE BERRY of Athens, Ga., died in Philadelphia on March 30. He was a recent graduate of the Jefferson Medical College.

Dr. JOHN EDGAR MARCH of St. John, N. B., died suddenly of cerebral hemorrhage on April 3, at the age of forty-seven years. He was graduated from the Bellevue Hospital Medical School and practised for some years in Hampton, N. B. He then removed to St. John, and in 1894 was appointed Quarantine Officer of the Port, a position he had held since that date.

Dr. GEORGE W. BIGGERS of La Grande, Ore., the father of Dr. George L. Biggers of that city, died on March 29 at the age of seventy-one years. He had practised in Oregon since 1848.

Dr. W. H. HARRIS of Belleville, Mo., died on April 3 at the age of sixty-five years. He was born in Meridian, Ala., and had practised in Belleville since 1884.

Dr. JUSTIN L. BARNES of this city, died on April 13 at the age of forty-seven years. He was graduated from Cornell University in 1881, and four years later received his medical degree from the New York University Medical School. He devoted himself to ophthalmology, and for many years had been connected with the Manhattan Eye and Ear Hospital. He was born in Middletown, Conn.

Dr. HENRY DEWITT JOY of West Brighton died of apoplexy on April 15. Dr. Joy was born in this city in 1841. He was graduated from Williams College and from the College of Physicians and Surgeons. For many years he was chief surgeon of the Pacific Steamship Line, and in 1900 he became consulting physician at the Sailors' Snug Harbor on Staten Island.

Correspondence.

JAPANESE LACQUER DERMATITIS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In your issue of January 12, 1907, is an abstract from an article in the *Medical Review of Reviews* by A. Hadden on Poison Ivy. I have not access to the original, but the abstract reads:

"The nature of this poison has not yet been clearly defined. On the leaf and stem of this vine (*Rhus toxicodendron*) there is a fine hairy formation on both the upper and lower sides. To this is attributed the chief agency of communication of the poison. Both flies and mosquitos are doubtless the carriers of these small hairy particles as well as of the sap to many sensitive skins."

Much of the Japanese black lacquer work is made with the sap of an allied plant (*Rhus vernicifera*) and a case has come under my care of severe rhus poisoning in a very susceptible individual from handling a box made of this material. It was not the patient's first experience of the sort and I have heard of other similar cases from the same cause. This would indicate that the hairs are at least not necessary to the conveyance of the poison, which appears to be contained in the sap and to retain activity after prolonged drying.

MANLEY F. GATES, Surgeon, United States Navy.

OUR LONDON LETTER.

(From Our Special Correspondent.)

INSANITY—SPIROCHETES OF RELAPSING AND TICK FEVERS—TYPHOID INOCULATION IN THE ARMY—MALARIA AND TROPICAL DISEASES—A QUASI-DIPHTHERIA BACILLUS—A TYPHOID BACILLUS FROM A SINUS—TUBERCULOSIS OF TESTIS—HOSPITAL FUNDS.

LONDON, March 29, 1907.

IN his concluding Lumleian lecture Dr. Savage dealt with alcoholism and influenza as causes of insanity. In respect to the first his conclusions did not quite accord with the common view, and he remarked that we have no proof that the abolition of alcoholism would diminish insanity. The recent increase bore no relation to the consumption of alcohol, for people were more temperate than formerly. According to the special report of the Irish Commissioners, excessive tea drinking should not be overlooked as a possible cause. At the same time he was obliged to admit that alcohol reduces the nutrition of brain and may be called a nerve toxin, and often thereby causes delusions, leading in bad cases to brain degeneration and premature senility. But a more potent factor, he held, was influenza. Some twenty-five years ago he had pointed out that this disease predisposed to nervous and mental disorders, but he was then scoffed at and told he saw insanity in everything—even influenza. His view was now widely accepted and he argued that influenza was a more active cause of insanity than all others. It produced insomnia and neuralgia and upset digestion, and so the nutrition of the brain was impeded and melancholia, mania, or dementia might be started. Acute insanity sometimes was seen in the early stage of influenza, but there was no special form of influenzal insanity, and though the disease often caused mental derangement it might sometimes exercise a modifying influence on those already insane. Dr. Savage believes a special receiving hospital in London such as Glasgow has would do good by sifting out acute and curable cases and saving them from being sent to asylums.

Sir K. M. Mackenzie, secretary to the Lord Chancellor, gave evidence on Wednesday before the Royal Commission on the feeble-minded. He had great confidence in the authorities in lunacy and a very serious question had arisen as to whether the Lunacy Commissioners were overworked. If the present system remained unchanged, some addition to their numbers should be made. He held that the Lunacy Commissioners should remain, in fact and in name, an independent body, and not become absorbed in a Government department. Lunacy was not a matter of policy, to be assigned to the Home Office, nor of sanitation, to pass under the local Government board. If it were classified with anything else it was more akin to the care of infants and the wards of court. But there were objections to transferring them to chancery.

Lieutenant-Colonel W. B. Leishman submitted some interesting observations on the spirochetes of relapsing fever and tick fever to the last meeting of the Pathological Society. His material included films from Austria, Aden, and India, as well as living organisms. He studied the development in white mice and found them equally fatal, contrary to the experience of others. The virulence was increased by passage, as shown by earlier appearance in the blood and more rapid multiplication. He could not confirm Novy and Knapp's description of morphological differences between the spirochetes of tick fever, European relapsing fever and Indian relapsing fever. He had found wide variations in each case, and they seemed to him due to such factors as the vitality of the organism, stage of the disease, method of fixation, etc. From the work of others he had no doubt of the specific difference between the spirochetes of tick and relapsing fevers. But further work seemed necessary to show if there were varieties of relapsing fever. Novy and Knapp consider these spirochetes to be true bacteria, but this view was not fully accepted by Colonel Leishman. He had not been able to demonstrate flagella in either, but he had observed the structure which Schaudinn considered was an undulating membrane in the organism of relapsing fever. This, as well as living organisms, were shown in a microscopical demonstration which followed the paper.

The progress of antityphoid inoculation in the army since the method was resumed on the recommendation of a committee appointed by the Army Council to investigate it, was described at the same meeting by Lieutenant-Colonel Leishman. Lectures are given to all drafts going on foreign service, and as far as possible the inoculations are carried out before embarkation, though sometimes the second is done on board—the vaccine being placed on every transport. Inoculation is also being widely tried in India and elsewhere, 20,000 doses of vaccine having been issued from the Royal Army Medical College during the last twelve months. Colonel Leishman and his colleagues have also carried on research work as to the method at the college without interruption, and he explained the methods of preparing and standardizing the vaccines. These had been prepared from typhoid bacteria killed at different temperatures by different chemicals, by desiccation, etc. Their several effects were tested on animals. In some instances where the results seemed promising similar tests were made on man. In the light of these researches the vaccine at present in use was obtained by a modification of Sir A. E. Wright's process. The bacteria were still killed by heat, but the temperature had been reduced to the minimum which would insure death in one hour, 53° C. The deleterious effects of higher temperatures had been shown during the experiments and it was suggested that some comparatively inferior results may have been due to overheating. The value of inoculation was seen in the case of a regiment which had been exposed to a severe epidemic of enteric. Out of a strength of 509 officers and men, 147 had been inoculated with the modified vaccine. There were 62 cases of enteric, with 11 deaths, all among the uninoculated, except 2, both of whom had declined inoculation, but both recovered.

We have had a good supply of contributions respecting malaria lately. I gave you some notice of a lecture by Prof. Ronald Ross in my letter of the 8th inst. and may add further examples. Dr. Lloyd Roberts of Liverpool read a paper to the Institute based on 124 consecutive cases treated in his tropical wards at the Southern Hospital. A lantern demonstration was given and the diagnosis between malaria and some other diseases dealt with. Dr. W. Canter suggested that it was time to discard the word malaria, which was a relic of the superstition about bad air He held the chief problems demanding solution were: (1) The occurrence of attacks years after leaving infected areas; (2) apparent immunity of exceptional individuals after repeated bites; (3) impossibility of employing quinine in some cases. He further said persistent vomiting sometimes rendered it necessary to give the quinine per rectum or subcutaneously. For coma he found the best treatment was blistering the shaven scalp, unless the temperature was very high, when cold baths were required in addition. In some chronic cachectic cases with acute exacerbations he had found Warburg's tincture useful if quinine could not be borne.

Major H. W. Grattan has read a paper at the Pathological Society on "blackwater fever," as observed in Sierra Leone. He said that in eight out of ten cases quinine had been taken before the onset of blackwater. Malarial parasites were found in the peripheral blood of 36 per cent. after the onset. The *Ankylostomum duodenale* was found in 50 per cent. The fall in hemoglobin and red cells was very great and absolute polynuclear leucocytosis was noted. No malarial parasites or pigment were found in the organs after death. He held the disease to be malarial because there was a previous history of malaria in every case, and the parasite was found in the blood in 36 per cent. of cases. Further, his opinion was that the disease was due to a special form of malarial parasite allied to, but distinct from, that of malignant tertian. He showed specimens of blood films containing parasites and charts illustrating the destruction and regeneration of the red cells and the hemoglobin.

The new society for promoting the study of tropical diseases may now be considered as successfully established. This "Society of Tropical Medicine and Hygiene" met at the College of Physicians on the 15th and completed its organization. The promoters hope to have an extensive membership, and as many of the most ardent workers reside abroad it will then be almost international in its scope.

Prof. Ronald Ross has to present in the Autumn a report to the International Congress of Hygiene at Berlin on the progress of antimalarial measures in British possessions and, if possible, in America. Let me ask the support on his behalf of those engaged in this campaign. He will be thankful for statements of the areas and districts dealt with, the exact nature of the measures employed, and any facts bearing on their results, addressed to him at the University of Liverpool.

Major W. S. Harrison showed the society a bacillus which microscopically resembled that of diphtheria. It was isolated from an old case of chronic suppuration of the middle ear. The organism produced involution forms very like diphtheria bacilli in agar. The differences in cultural reactions were described. Major Harrison also exhibited a typhoid bacillus isolated a year after typhoid fever from a sinus which followed a post-typhoid abscess. This organism formed long, involuted strings, like typhoid cultures on malachite green media; it gave all the cultural character of typhoid bacilli and was agglutinated by an antityphoid serum. The patient's serum agglutinated other strains of typhoid bacilli in 1 to 200 to 1 to 400, and his own strain in 1 to 1,000; its phagocytic ratio was two to four times as great for other strains and forty-six times greater for his own than normal. It was very resistant to phagocytosis in normal serum. It seems difficult to account for the persistence of the organism in the body of a patient whose serum had such a high phagocytic ratio for typhoid bacilli.

Tuberculosis of the testis is so rare in infants that you may be interested in a paper on the subject read at the Children's Society by Mr. Russell Howard. He found the percentage compared with all surgical cases in the London Hospital during ten years had been .07. In adults the percentage was .33. The disease is primary in the epididymus, spreading thence to the body of the testis. The vesiculæ seminales and prostate are very rarely affected. The left testis is most often attacked, the undescended testis seldom. Hydrocele occurred in a third of the cases. The diagnosis from syphilis is difficult and chiefly rests on indirect evidence and the effects of treatment. Tuberculous peritonitis is a rather frequent complication. If treatment be without effect and only one testis affected, it may be removed without bad effect; but if both be involved, ablation would only be justifiable as a last resource on account of the impairment of bodily and mental vigor produced.

The thirty-third annual report of the Hospital Saturday Fund records steady progress. The income in 1906 was £26,460, as against £25,930 in 1905. The board approved a distribution of £23,898 among 205 institutions.

The Birmingham fund is the next largest to London, for last year its collection exceeded £19,000, and this year it is hoped still more will be raised. The other Saturday funds amounted to £10,981 at Leicester, £10,279 at Leeds, £8,276 at Liverpool, £4,608 at Manchester.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

FOURTH ANNUAL MEETING OF THE PHILIPPINE ISLANDS MEDICAL ASSOCIATION—A SPIROCHETE IN YAWS—CESAREAN SECTION UNDER DIFFICULTIES—TYPHOID FEVER—HAWAIIAN FEVER—X-RAY TREATMENT OF LEPROSY—PERSONAL.

MANILA, P. I., February 16, 1907.

THE fourth annual meeting of the Philippine Islands Medical Association will take place in Manila from February 27 to March 2, sessions being held daily during that period. An interesting program has been prepared. Among the papers to be read will be "The Pathologically Active Constituents of Some Philippine Medicinal Plants, Arrow Poisons, and Fish Poisons," by Dr. R. F. Bacon of the Bureau of Science. Another paper, entitled "The Transmission of Leprosy to Apes," by Moses T. Clegg of the Bureau of Science. Another, "The Fate of the Agglutinins upon Filtering an Immune Serum," by Dr. R. T. Edwards. Another, entitled "Observations on the Etiology of Dengue Fever," by Dr. Percy M. Ashburn, Assistant Surgeon U. S. Army, and 1st Lieut. C. F. Craig, U. S. Army, both members of the Army Medical Board for Tropical Diseases. It is understood that some new data upon the transmission of this disease will be presented. Another paper, "A Summary of Experimental Work on Plague Immunity," by Dr. R. P. Strong.

A number of distinguished foreign guests have accepted invitations to be present. Among these will be Dr. J. M. Atkinson, the Honorable Principal Civil Medical Officer of Hongkong; Dr. W. V. M. Koch, Medical Officer in Charge of Infectious Disease Hospitals, Hongkong; Dr. Sia Tien Pao, Delegate from His Imperial Chinese Majesty's Government; Dr. Kannosuke Myajina, Delegate from His Imperial Japanese Majesty's Government.

The regular monthly meeting of the Manila Medical Society was held at the St. Paul's Hospital, February 4, 1907, at 8:30 P.M. Dr. Ashburn of the Army Board of

Tropical Diseases showed a number of interesting microscopical specimens. Among others were some spirochetes, which were taken from some cases of yaws found in Manila. From microscopical examination, the organisms could not be distinguished from the ordinary *Spirochæta pallida* of syphilis, and they corresponded very closely to the spirochetes described by Celli of Colombo.

A paper prepared by Dr. Frank T. Woodbury, Captain and Assistant Surgeon U. S. Army, upon "Performing Cesarean Section Under Difficulties" was read before the society. It was another practical demonstration of what may be accomplished when the rudiments of aseptic surgery are observed, even though the operation is performed in the interior of a sparsely inhabited tropical island, without proper instruments or surroundings usually deemed necessary in such cases.

Within the past few weeks about ten cases of typhoid fever have been reported in the city of Manila, which, upon investigation, all proved to be positive to the Widal reaction. An investigation is now being made with the hope of ascertaining the source from which the infection in these cases was derived. The investigation, so far, shows that long before the American occupation, typhoid cases were found, from time to time, but there did not seem to be any tendency for the disease to spread. On account of the very few cases that occur, the water obtained from the city mains can almost be dismissed from consideration. It is hoped that this inquiry will throw some light upon the fact as to whether typhoid does not spread as rapidly in tropical countries as in temperate ones, on account of some climatic condition, or whether it is perhaps due to the fact that the means or vehicles for the transmission of the disease are not present. This latter view would appear tenable, especially in Manila, where, up to a few years ago, very little fresh milk, oysters, or other shellfish likely to become infected have been used, but both are now coming into general use, and it may possibly be that the present increase in typhoid fever in Manila can be attributed to that fact.

During the past few weeks there have also been a number of cases of obscure fevers observed, which in their general symptomatology resembled somewhat the so-called Hawaiian fever, which has been described as occurring in those islands. The onset is much more rapid than in typhoid fever, the prodromes lasting a week or less and are generally characterized by general malaise, pain in the joints and limbs, which lasts about a day, no headache, moderate pain in and behind the eyes; bronchitis often occurs after the onset of the disease. The digestive disturbances are not very marked, the appetite, in most cases, remaining fair. The fever rises gradually for the first week to about 104, and then drops within forty-eight hours to normal, leaving the patient in much the same exhausted condition as found in certain forms of influenza, in the United States. In some of the cases the disease appears to localize itself in the larynx and the upper air passages, causing intense congestion, and sometimes complete loss of voice for about a week. There are no rose spots, occasionally there is nose bleed; the spleen appears not to be enlarged. Bacteriologically the condition does not correspond to para-typhoid. Careful examinations have failed to show any malarial organisms or other blood parasites and the Widal reaction is absent, while the diazo is present. The occurrence of these obscure fevers again emphasizes in a forcible manner the necessity and advisability of undertaking additional research work in order that the etiology and pathology of these unusual diseases may be better understood. Of the twelve patients referred to herein, two died, but it was not possible to obtain an autopsy.

One of the lepers, who has been mentioned heretofore, from time to time, as having undergone treatment by the *x*-ray at the San Lazaro Hospital, and having once been apparently cured and remained so for a period of nine months, after which time he again showed leper bacilli in skin scrapings, has been under *x*-ray treatment for the past two months, and is now again, so far as can be determined by microscopical examination, entirely free from the disease. It is the intention, this time, to continue the treatment at intervals for at least a year or more, after which it is proposed to treat him at intervals of three months. The general principles upon which the treatment is to be applied this time will correspond closely to the method of treating syphilis with mercury, which is recommended by many standard syphilographers.

Passed Assistant Surgeon Carroll Fox of the Public Health and Marine Hospital Service, who has been on duty as Quarantine Officer in the Philippine Islands for the past four years, during three of which he was stationed at the port of Cebu, has been relieved and returned to the United States.

Passed Assistant Surgeon Thomas B. McClintic, and Assistant Surgeons W. F. McKeon and Joseph Pettyjohn, of the Public Health and Marine Hospital Service, in compliance with orders of the Surgeon-General, have arrived in the Philippines and been placed on duty as quarantine officers at ports of entry.

Progress of Medical Science.

New York Medical Journal, April 6, 1907.

Endemic Neuritis.—In this issue J. M. Wheate concludes an article on endemic neuritis, contributing some observations hitherto unpublished, and reviewing recent researches and opinions of recent investigations by various authorities. His own observations were made in the Philippines in connection with his army medical service. His general conclusions are as follows: (1) Beriberi is an acute infectious disease, transmitted by direct infection, probably always through a skin abrasion upon some vulnerable part of the body. (2) The specific organism causing the disease is an exceedingly small bacillus, usually seen in pairs but not encapsulated, and is found in the cerebrospinal fluid and blood only during the acute or inflammatory stage of the disease, after which time it rapidly disappears from these tissues. (3) The favorite habitat is virgin soil protected from sunlight. It is a slightly facultative anaërobin and not very viable, being speedily killed by exposure to sunlight as demonstrated by bacteriological test and by clinical experience. (4) The former classification of the disease as beriberi hydrops and beriberi atrophica is erroneous. There is but one form of beriberi, which is characterized by three stages: First, the stage of invasion; second, the stage of exudation, beginning in the cord and following by toxic motor and sensory paralysis of varying extent, which in typical cases proceeds to the third, or the stage of compensation, in which the disappearance of the bacilli and the toxic stage results in the rapid (usually) disappearance of the dropsy in cases in which softening and dilatation have not progressed to the degree of permanent loss of compensatory action. (5) The degenerative cord and nerve lesion is long present in all moderately severe cases, resembling the lesion in tabes in this particular, and even though the heart lesion appears to have subsided while the patient is leading the inactive life of a convalescent, the damage to function is permanent. This explains the numerous cases of sudden and unaccountable death in patients leaving hospital apparently cured, as reported by many observers with extensive hospital experience. (6) That a toxin or toxalbumin should be isolated is the rational conclusion, and that an antitoxin curative in the period of germ activity and before degenerative change has taken place is the inevitable reward for properly directed effort.

Spondylose Rhizomelique.—A further contribution to the study of this malady is made by A. Gordon, who presents the clinical histories of two personal cases. In the first case there was rigidity of the lower part of the spine and a kyphosis at the same level. Symptoms of involvement of the spinal cord and of the roots were very evident. A rheumatic family or personal history was wanting, while the general condition of the patient had been stationary from the onset of the disease. In the second case there was a marked rigidity of the lower spine and an ankylosis of the large proximal joints of the lower limbs. Pain was present in both extremities and in the back. Cord involvement was also evident, and in contrast with the first case in which all the reflexes were abolished, they were here exaggerated, pointing to an involvement of a different tract in the cord. Rheumatic history was wanting. The essential pathological feature of this curious affection seems to be an ossification of the periarticular ligaments of the spine and hypertrophy of the articular processes which come into immediate contact with each other after the last vestige of the cartilages has disappeared. According to the author, the disease can hardly be considered as a pathological entity. It is probably not of rheumatic origin. Two types of the affection have been described. In one there is ankylosis of the cervical spine with meningomyelitis. In the other there is spinal ankylosis and ankylosis of the large proximal joints of the lower extremities without cord involvement. The author states that the idea of uniting all forms of spondylosis in one cannot reasonably be accepted, and the term "spondylosis" should be reserved only for the purpose of designating the symptom, rigidity of the spine, and the original name given by Bechterew, Strümpell, and Marie be abandoned. Spondylosis is

only a symptom of a more complicated disease, and the frequent involvement of the cord shows that the etiological factor is of a more complicated order than one may suppose.

Eructations in Heart Patients.—This question is considered by F. Schwyzer, who finds the condition more common in old cardio- and arteriosclerotic patients. The presence of gas in the stomach may be the most troublesome symptom complained of. The gas arises first of all from fermentation, and the impaired abdominal circulation prevents the gas from being taken up by the blood and carried to the lungs for exhalation. It may also be true that defective abdominal pressure is operative in old persons whose abdominal muscles are getting flabby. So also some of these patients seem to swallow considerable ordinary air. Irregularities in the intestinal circulation lead to abnormal condition of the gastrointestinal fluids. The result of insufficient circulation in the intestinal tract brings on a condition which we may call intestinal dyspnea. Locally diminished blood or oxygen supply of the gastric or intestinal wall causes peristalsis or contraction, until the smooth muscular fibers become exhausted and relax. Thus the stomach reacts with contraction on momentary insufficiency of its circulation, while the heart under the same conditions causes more or less intense pain and oppression. If the gastric circulation is seriously insufficient, the stomach will react very soon after a moderate quantity of food has been taken. The patient will feel the pressure in the stomach, he will expel some gas, and his appetite will be satisfied too soon. If the circulation in the gastric wall is fairly sufficient, the patient will be able to take quite a large meal; he will eat as much as the stomach will hold, and then when gastric fermentation sets in and begins to distend the stomach still more, the border line of sufficiency in the circulation will be passed and gastric symptoms will show themselves. Still another causative factor may be exercise during the height of digestion.

Journal of the American Medical Association, April 13, 1907.

Internal Hydrocephalus.—W. J. Spiller and A. R. Allen discuss the causes of internal hydrocephalus, reviewing the literature, and remark that while the occlusion of the aqueduct of Sylvius is not infrequently mentioned as an etiological factor in the text-books, it is rare to find references to actual cases of such occurrence. They take the opportunity, therefore, to report a case in which the condition was induced by a probably congenital, almost total occlusion of the aqueduct. The subject was an elderly woman who was supposed to have been born hydrocephalic, but in spite of this and of an epilepsy that had lasted for years she had lived to the advanced age of sixty-two, and retained her faculties fairly well-developed. The aqueduct, while almost entirely occluded, was well-lined throughout by a layer of ependymal cells which would not be the case had its occlusion been due to neuroglia proliferation, as in a previous case reported by Spiller. This, and the long continuance of the condition through the patient's whole life, indicates the congenital nature of the obstruction.

The Pathology of Paralysis Agitans.—C. D. Camp, after giving a review of the literature of the pathological findings in the nervous system in paralysis agitans, reports the results of his examination of fourteen cases, in eight of which he was able to study the peripheral nerves and muscles, and in two the ductless glands also. The most constant lesion in the nerve centers was a fibrosis of the capillary blood-vessels of the spinal cord, which by rendering them more prominent, caused them to appear more numerous. The posterior and lateral column regions seemed most involved. There was no degeneration of nerve fibers of the cord in any case, and in only two cases was this observed in the peripheral nerves with the Weigert hematoxylin stain; in two others there was a swelling of the myelin sheaths, accompanied in one case by swelling of the axis cylinders. There was considerable pigmentation of the Betz cells in the paracentral lobule, but in only two cases were distinctly degenerated cells observed. He discusses the various theories of the disease, and thinks that many of the pathological conditions found, and to which the disorder has been attributed, are only coincident senile changes. The muscular theories are also discussed, and in nine cases in which he examined the muscles, one of them during life, he found pathological changes in all. There was swelling of the fibers, which were round in cross-section instead of polygonal, multiplication of nuclei, etc., his findings agreeing in the main with those of Schwenn, Schiefferdecker, and Idelsohn, indicating, he is inclined to believe, a specific change in the muscles in paralysis agitans, though he admits that this is not yet definitely proven. Camp, in considering the pathogenesis of the affection, finds most reason to believe that it is due to a toxemia, and that this is connected with disordered parathyroid function. In the two cases in which he was able to examine the ductless glands he found the parathyroids in a decidedly pathological condition; in both there was a peculiar fatty infiltration, especially in relation to the blood-vessels. Such a finding, in connection with the experimental evidence as to the effect of parathyroidectomy and the therapeutic results of Berkley in the treatment of paralysis agitans with parathyroid extract, furnish, he thinks, strong proof that the parathyroids play an important part in the pathogenesis of paralysis agitans. His conclusions are given as follows: 1. Paralysis agitans is not a neurosis nor is it senility. 2. The anatomic basis of the symptoms, muscular rigidity, tremor and the symptoms dependent on them, lies in the affection of the muscles. 3. The disease is probably a general toxemia, and there is evidence that it is due to alteration in the secretion of the parathyroid glands. The case histories of the patients of which Camp made the pathological studies are appended to his article.

Acute Otitis Media.—W. J. Leach describes acute middle ear disease, its symptoms, course, and treatment. In case palliatives fail and bulging of the drum and pain increase after thirty-six hours' treatment, he advises the immediate performance of myringotomy as lessening the danger of invasion of the mastoid cells, and after cleansing with peroxide of hydrogen and mopping out with dry cotton, filling the canal one-third full of boric acid, and inserting a cotton plug. After the discharge has ceased he would use 10 per cent. ichythol in liquid vaseline until the wound is healed, careful attention being given to nasal and pharyngeal conditions. The treatment should be carried on directly by the physician, and Leach emphasizes this as an essential. If intrusted to others it will not be well done. The prognosis of acute otitis media is good, he thinks, if the condition is promptly treated, but when the mastoid cells are involved the prognosis becomes serious. The way to success in otology is never to let acute otitis become chronic.

Physiological Action of Alkaloidal Salts.—O. H. Brown remarks on the common notion that different salts of an alkaloid have a similar quantitative effect, and says that he has long been of the opinion that the effect varies with the acid with which the alkaloid is combined. He describes his method of experimentation, in which he tested various solutions of the easily obtainable salts of morphine, strychnine, and quinine as to their activity in the destruction of paramecia. A simple unicellular organism of this kind gives more accurate results than would a more complex one, and the strength of the solution and the time required to destroy their active movements, which are always visible during life, are easily observed with low power of the microscope. The results are given in tabulated form, and show a striking difference in the action of different salts of the same alkaloid, and it is a rather interesting fact that the paramecia of the same culture and of different cultures, varied considerably in their susceptibility to the same solution. This was specially noticeable with those solutions that required some time to produce toxic effects; in the more rapidly acting ones it was scarcely noticeable. He sums up his results as follows: The acid with which certain alkaloids, strychnine, quinine, and morphine are combined alter decidedly the pharmacological action of the alkaloid—at least, in regard to their toxicity for paramecia. The most toxic salts of strychnine and quinine are in some instances, at least, those which stimulate catalytic processes the most markedly. The salts of morphine with the smallest degree of toxicity, in some instances, are the salts of those acids, the sodium salts of which stimulate the catalysis the most markedly.

Holes in the Mesentery.—G. K. Dickinson reports two operations in which intraperitoneal hernia through holes in the mesentery was found to exist, and remarks on the comparative rarity of the condition. He attributes the occurrence of the holes to defective arterial supply; they are usually found in the mesentery near the cecal region where the anastomosis of the ileocolic branch of the mesenteric artery with the intestinal branches is sometimes so incomplete as to make it impossible to inject this area.

Blood Pressure in Arteriosclerosis and Bright's Disease.—A. R. Elliott reports and discusses the variations in systolic blood pressure in certain cases of arteriosclero-

and chronic renal disease which had been under routine observation for considerable periods of time. The gauges used were Cook's modification of the Riva-Rocci apparatus with a 9 cm. arm band and Stanton's sphygmomanometer. The great majority of the observations were taken with the patient in the sitting position, the exact conditions were sought to be duplicated and physical repose and mental tranquillity of the subject under observation, so far as possible, were secured. In thirty cases of arteriosclerosis observed in this way, in only six (20 per cent.) was there a positive hypertension. This high percentage of cases without excessive tension shows that the degree of sclerosis of superficial arteries is no criterion of the severity of the sclerosis of visceral arteries or of the degree of tension present. If we can exclude chronic nephritis when high blood pressure and cardiac hypertrophy develop, we have reason to suspect splanchnic or aortic sclerosis. Sixty cases of chronic Bright's disease were also observed, and the high average blood pressure in these (190 mm.) was in marked contrast with the cases of arteriosclerosis. No constant ratio was observed between the degree of blood pressure and the intensity of the albuminuria or the amount of urine excreted. High tension in Bright's disease is in a way compensatory, but it needs watching. The first indication is to reduce, if possible, the systemic toxemia, and diet, fluid intake, elimination and personal hygiene generally must be looked after. The question of special vascular medication, however, is discussed. Before giving vascular drugs, ascertain thoroughly the cardiac and circulatory conditions; high pressure does not always require reduction by drugs. In emergencies, such as angina pectoris, apoplexy, etc., they may be called for. A sustained high pressure, with disquieting symptoms, may call for vasodilator medication, but it should be given cautiously, watching the effects. A fall of 10 or 15 per cent. is all that it is necessary or judicious to produce. The benefit from such medication must not be estimated by the blood pressure record, the patient's comfort, and the pulse rate are better indications of the effect produced. The use of vasodilators in the late stages of Bright's disease, with cardiac dilatation, dropsy, etc., is practically useless.

Points Regarding Opsonins.—Experiments to determine a number of points regarding opsonins were performed by E. A. Knorr, who finds that the phagocytic cells are, generally speaking, in direct proportion to the strength of the bacterial emulsion; that both undergo a distinct increase with long exposure, the maximum being reached in one hour. After two hours the degenerative changes in leucocytes render accurate observations impossible. Phagocytosis does not occur at room temperature, but an exposure of fully six hours is required to make it as noticeable as it usually is after fifteen minutes at body temperature. As regards the effect of the number of persons composing the pool, he concludes that a simple, or at most a double-mixed pool is necessary for ordinary purposes, a conclusion he believes Wright himself has reached. Aging of the culture does not lead to a drop in the phagocytic or percentage index, and boiling, thymol, and chloroform do not appear to have any inhibitory effect on the opsonic values, while lysol seems to produce a decrease. His experiments show that the serum loses one-half its opsonic power in twenty-four hours, and that after this there is no apparent change for the next twenty-four hours; then there is a rapid drop, but it does not wholly disappear until after five days. This is with serum collected and kept in a sterile condition. The corpuscles rapidly lose their capacity for phagocytosis, and only fresh ones can be used in opsonic work. Knorr's experience is that after six hours many of them are dead, and fallacious results are obtained if such are used. With weak emulsions the chances of error are greater than with strong emulsions, keeping in mind the fact that with too rich emulsions counting becomes difficult if not impossible. In many of his experiments the advantage of Simon's percentage index over the bacillary index of Wright are, in his opinion, very clearly shown.

Accidental Plague Inoculation.—P. C. Freer gives an account of the accidental inoculation with plague of a number of Philippine natives which occurred in the course of a very successful series of anticholera vaccinations. The cholera vaccine that had been used consisted of an extract of the killed, digested and filtered organisms, later modified to a mixture of such an extract with one obtained by shaking—in a machine—the living organisms in distilled water and then filtering. The reaction that follows the use of this vaccine is less severe than that frequently following smallpox vaccination, and yet a high degree of blood immunity is produced. It being thought desirable to test the method recommended by certain German authorities of using the whole organism and not its extracts, it was necessary for this purpose to inoculate immediately with a mixture of fresh twenty-four-hour cultures in saline solution, and inoculations were made for several days without accident. It is supposed that on the day that the accident occurred some unknown person misplaced a tube of virulent plague culture, which closely resembled the cholera cultures, among the latter, as such a tube was found missing from the incubator in which the plague cultures were. The matter was thoroughly investigated and these facts developed. It must be understood that the regular anticholera vaccine had absolutely no connection with the accident, the mixture responsible being an altogether different thing. Its microscopic examination revealed no plague bacilli, but guinea-pig and monkey inoculations were followed by the disease.

The Lancet, March 30, 1907.

Certain Acute Infective or Toxic Conditions of the Nervous System.—In the third Goulstonian lecture, E. F. Buzzard refers particularly to acute ascending myelitis, Landry's paralysis, and acute toxic polyneuritis. Three clinical histories are given under the third of these classes. Here it is natural to suppose that the poison at work is carried by the blood, and that the parts innervated by the gray matter of the cervical and lumbar enlargements suffer more than those in similar connection with the dorsal region. At the same time the whole of each lower motor neuron, including both the cell and its axion is exposed to the poison in the general circulation, and in these circumstances the particular affection of the long processes to the periphery of the limbs has an explanation offering some degree of probability. In one of the author's cases of Landry's paralysis, he found cocci in the extradural tissues, and it is quite conceivable that infection either by the cocci or by their toxins could take place from those tissues into the extramedullary and intramedullary lymphatics. From the absence of actual organisms in the spinal tissues in most of these cases it is probable that the toxins play the most important part in this infection. Allowing for a moment that this theoretical process can take place, it must be granted that an explanation of the gradual, ascending, step by step, involvement of the central nervous system is provided, and one which makes the more progressive and even distribution of the palsies more readily understood. This theory does not necessarily presuppose that the blood is free from the responsible organism nor that the extradural tissue is its only resting place, but it suggests that there may be places where the bacteria may find suitable lodgment for the purposes of multiplication and whence they may pour their toxin into the spinal lymphatic system.

British Medical Journal, March 23 *and* 30, 1907.

Removal of Enlarged Tonsils.—R. Maclaren prefers deep anesthesia, the patient being laid on one side. The instruments used are a gag, straight vulsellum, blunt dissector like a periosteum elevator, scissors curved on the flat, scalpel, probe-pointed bistoury, and forceps for holding tampons. The operation is commenced by opening the mouth as widely as possible with the gag. The tonsil of the side on which the patient is lying is then caught by the vulsellum. The best grip is got by placing one blade on the nasal and the other on the laryngeal end of the tonsil. The tonsil is drawn inwards and forwards. If it comes out from between the pillars no knife need be used, but if a considerable part of it remains behind the palate a transverse incision is made to expose the gland thoroughly. This is done with a sharp pointed scalpel from within outwards through the mucous membrane. It starts about the middle of the anterior pillar and is from half to three-quarters of an inch long, according to the size of the tonsil, which is made to bulge through it. At this stage, whether the mucous membrane has been cut or not, as much traction is put on the gland as it will bear and the blunt dissector is pushed behind it from above. It is then systematically teased out from its connections. There is this distinct advantage in starting in this way, that it prevents the uvula being injured, as it might be if the gland were taken out from below. Most tonsils peel cleanly out with a smooth and rounded back surface. Much of the completeness and facility of the operation depends on the consistence of the gland. If it is firm the removal is easy, but if it is soft and bears traction badly it may be a matter of difficulty to get it out whole owing to the teeth of the vulsellum tearing through. Scissors or the blunt bistoury are very useful for a tonsil of this latter sort. It is first well loosened by the dissector, and then

its final attachments snipped or cut. When one tonsil has been removed it is advisable to wait for a few minutes to allow bleeding to diminish. The second tonsil is then dealt with in a similar way and adenoid growths and turbinate thickening attended to if necessary.

Infiltration Anesthesia in Major and Minor Surgery.—This method of anesthesia is strongly commended by G. J. Arnold, who says that the resirable qualities of solutions for this purpose are as follows: (1) The percentage of the active agent contained in the solution must be sufficiently high to render the fluid efficient as an anesthetic, but the total quality of fluid infiltrated from beginning to end of an operation must contain an amount of the active agent insufficient to give rise to toxic results. As a corollary, it follows that solutions of cocaine are inadmissible unless only a small quantity of fluid be required, since it is not safe to inject more than about one-quarter grain of this substance. (2) The solution must be sterile, which is nearly equivalent to saying that its active agent should be capable of being boiled without impairment of its anesthetic properties. (3) The third essential of the solution on which stress must be laid concerns its physical and physiological features. It must be as nearly as possible isotonic with the tissues. The author fully describes the technique of the process used and states that his own list of operations by this method included the following: Gastrostomy (by the Ssabanajew-Frank method). Herniotomy (three cases); appendectomy in a quiet interval. Laparotomy for intestinal obstruction. Laparotomy with resection of small intestine and end-to-end anastomosis. Suprapubic cystotomy. Closure of an artificial anus (preliminary colostomy). Radical cure of hernia. Radical cure of varicocele. Removal of a mass of suppurating tuberculous glands in the groin (in an old and debilitated patient). Extirpation of the saphenous vein in the thigh and its tributaries in the leg for varix (many cases). Numerous minor operations for the removal of cysts, lipomata, needles, etc.

The Calcium Salts as Heart Tonics.—W. Ewart expresses the belief that so long as we continue to prescribe calcium salts to favor coagulation, there would seem to be some inconsistency in recommending them in a disease like pneumonia, for instance, which is so prone to clotting that one of its common fatal terminations is intracardiac thrombosis. Our cardiac stimulants should be sought in some other direction. As a fact, the danger special to pneumonia is not so much a clotting in the vessels as that within the alveoli; and the worst danger for the patient is the attitude of expectancy which watches the progress of his "consolidation" as though it were a fated fulfilment, instead of hastening to forestall it by defibrinating treatment. The prevailing neglect of this early and only opportunity of influencing the disease accounts for the uniformly neutral results from various lines of medication, which are all likely to be inoperative after consolidation has set its seal upon the case. Happily those therapeutic and dietetic measures which are indicated, whilst they are in themselves harmless, are demonstrably of service, and effectual in proportion to the early date of their adoption. Their aim is to maintain in the congested areas as much fluidity of blood and lymph as possible, to prevent vascular and lymphatic obstructions, and thereby to promote a steady rate of elimination of the iniecting agents and of their toxins, thus avoiding or lessening the possible disaster consequent upon their concentration. In view of these indications calcium chloride can have no place in our treatment of the early stages, but there remains the more urgent duty of relieving local congestion by leeches, of withholding fibrin formers from the fever diet, of stimulating excretion in every way, including cardiac stimulation; and, lastly, of administering freely the citrates and iodide of potassium to reduce the viscosity of the blood, unless we should discover some better means of checking the deposit of fibrin and of furthering its reabsorption before it has become completely solidified.

Operative Treatment of Ascites.—In a paper presented to the London Medical Society, Laurence Jones said that the actual cause of ascites occurring with hepatic cirrhosis was still doubtful. Both portal obstruction and toxemia seemed to play some part, and it alone was unable to reproduce the effusion if the portal vein was able to produce ascites only when a certain grade of toxemia was present, but that the toxemia alone was unable to produce the effusion if the portal obstruction was relieved by the formation of fresh portocaval anastomoses. Chronic peritonitis, although often associated with ascites, was not necessarily the primary cause. The patient most suitable for operative treatment was one who had survived the tapping of a fluid shown to be of mechanical rather than of inflammatory origin, whose liver was in the hypertrophic stage, who was still fairly young, and whose symptoms were more those of toxemia. The common object of all operations was to increase the communications between the portal and caval systems; the omentum was the portal area usually selected, and it was sutured to the abdominal wall outside the peritoneum, as in the operations of Schiazzi, Bunge, Pascale, and others, or inside the peritoneum as in the original operation of Monson. The operation as devised by Monson seemed still the best. Various additions, such as hepatopexy and splenopexy had been made to simple fixation of the omentum or had been performed where the latter had failed or had been impossible. The operation certainly relieved the patient in many cases of the ascites and thereby prolonged life in comfort for some years; occasionally the condition of the liver itself appeared to have improved, but that effect was not claimed for the operation, and it was not possible to explain any such result. About one-third of the patients died within one month of the operation, about one-third were definitely improved and their lives were prolonged for some years, and about one-third were improved but slightly or not at all. The death-rate due to the operation should not be more than 10 per cent.

Bacterial Diagnosis of Cholera.—M. A. Ruffer summarizes an extensive series of investigations on this subject, and describes the technical methods followed. The investigations were carried on at Port Said, and they justify, according to the author, the following conclusions: (1) A certain number of vibrios, although agglutinating to some extent with cholera serum, are sharply differentiated morphologically from the cholera vibrio, by the fact that they are multiciliated. (2) Whereas some vibrios found in ship water are agglutinated by very dilute solutions of cholera serum, others are agglutinated by far stronger solutions only. The latter form a transition stage, so to speak, between the nonagglutinating and the highly agglutinating vibrios. (3) Although an active cholera serum agglutinates all the vibrios to some extent, yet only two of these vibrios when injected into animals produce serums having a powerful agglutinating effect on cholera vibrios; two serums had the same property but to a slighter extent, and two had none. These experiments, therefore, support the conclusion previously arrived at —namely, that it is not advisable to trust to the agglutination test only in the bacteriological diagnosis of cholera. The test is useful but not specific.

Diagnosis of Certain Forms of Renal Disease.—In the course of an interesting paper on this subject, J. R. Bradford expresses the opinion that nephritis of the parenchymatous or diffuse tubal type is by no means uncommon in the first two years following syphilitic infection. It often comes on at a time when the patient feels perfectly well, is not deeply modified by the underlying dyscrasia, and hence is commonly referred to exposure to cold. Examination may show a few spots suggestive of syphilis or even a gumma. This form of nephritis is characterized by very intense albuminuria, the urine frequently becoming solid, although the patient may not seem very sick. Consequently the disease comes to light unexpectedly. Albuminuria also is persistent, lasting several months, but it may entirely clear up. Nephritis may also occur during the course of secondary syphilis and be of an intense type. Probably all cases of renal disease are ultimately due to toxic agents rather than directly to exposure to cold. Syphilis may supply the toxic factor.

Berliner klinische Wochenschrift, March 18 *and* 25, 1907.

Hyperemesis Gravidarum.—Baisch finds that all these cases can be included in one of three types as regards their source—they are gastric, central, or uterine. That depending on a nervous basis probably is the most frequent, and among the twenty cases personally observed by the author fifteen may be included in this category. In the latter class of cases the prognosis is better than in the others. In addition to suggestive and medicinal treatment, operative procedures should always be considered in those patients who do not respond readily to the former. The writer thinks that the best means of deciding when the medical treatment is to be superseded by the radical is the weight scale. If there is a progressive loss in weight, as shown by weighing done twice a week, the uterus should be immediately emptied. He claims that the dictum stated by Freund, to wait for edema, convulsions, and mental confusion, is entirely false. Abortion, when decided on, should be carried out with the least expenditure of the patient's energy, and the technique should be simple

enough to preclude any danger from infection. The writer prefers to introduce a laminaria tent after sufficient dilatation of the cervix by graduated dilators. This produces sufficient dilatation to permit the removal of the fetus with the ordinary Winter's forceps. The manipulations are not extensive and in most cases the operation may be done without anesthesia.

A Case of Hepatic Abscess Containing Typhoid Bacilli.—Venema and Grünberg report a case in which during an attack of typhoid an abscess developed in the right lobe of the liver which was evacuated with good results. The pus from the abscess was carefully examined and the *Bacillus typhosus* obtained in pure culture. Only five cases in which a definite bacteriological proof is at hand are to be found in the literature. The prognosis is very unfavorable, the mortality amounting to about 66 per cent. The treatment can only be surgical, and the result depends on whether we have to deal with single or multiple abscesses. In the latter case, where the condition is evidently the result of a pyelophlebitis, surgical interference is naturally useless, but in the former a good result may be expected.

An Epidemic of Meat Poisoning in Berlin.—Jacobson refers to an epidemic of poisoning cases during a short period, in which ninety persons living in a restricted area were taken with symptoms of an acute intoxication or infection, which was traced to the meat consumed by these people. Two fatal cases are included in the number. The meat in question appeared to be in good condition, and there was nothing in the odor, taste, or consistency to give rise to any suspicion of its poisonous character. The symptoms came on within eight hours after eating, and were most severe in those persons who had eaten the meat raw. Examination of the tainted beef showed that it contained the *Bacillus paratyphosus.* This organism was later also obtained in pure cultures from the stools of the affected individuals. The symptoms were those associated with a paratyphoid infection. The source of the infection of the meat itself could not be traced with any certainty.

Münchener medizinische Wochenschrift, March 12 and 19, 1907.

Scopolamine Morphine Narcosis in Labor.—Bass publishes a report of 107 cases of labor conducted with this method of anesthesia. As the result of his observations he claims that the pain of the labor may in the large majority of cases be alleviated in a marked degree. For the purpose indicated a dose of 0.0003 gm. scopolamine and 0.01 gm. morphine was found to be sufficient, and any increase in the size of the dose did not improve the results. In some cases a delay in the labor occurred, but this did not appear to have any bad effect on either the mother or the child. The uterine contractions and the placental delivery were not apparently affected, but the abdominal expulsive efforts were considerably inhibited. In no instance were any undesirable after-effects noted as regards the mother, but the result on the child must not be regarded with indifference. In one case the death of the fetus may have been due to this procedure, and for this reason considerable care should be exercised in administering an otherwise valuable combination of drugs.

On the Course of Urobilinuria in Typhoid.—Rubin reports his observations on this phenomenon in a series of eight cases. For the purpose of making the test he employed Schlesinger's reagent, which consists of a ten per cent. solution of zinc acetate in alcohol. Equal parts of urine and reagent are allowed to stand for twenty-four hours, and after fluorescence appears the specimen is subjected to spectroscopic examination. Rubin's results agree in the main with those of Hildebrandt. The appearance of a well marked urobilinuria at the beginning of defervescence may be regarded as an evidence of a favorable outcome. If the phenomenon continues during convalescence in any given case, care should be taken in increasing the patient's diet or allowing him to get up. Not until the test is negative is it apparently safe to discharge the patient.

The Indications and Technique of Extirpation of the Lacrymal Sac.—Bäumler reports a aseries of 350 cases in which this operation was done. The operation of extirpation is indicated in all cases where the removal of the infectious focus is necessary in order to protect or preserve the eye, or where the presence of a chronic dacryocystitis has resisted all other forms of treatment. In doing the operation it is necessary to remove not only the diseased sac, but also the surrounding tissues, particularly the periosteum. In most cases the after-treatment may be conducted as an ambulatory one. The final results in this series of cases were excellent, and in only a few cases did primary union of the wound fail to take place.

Polyserositis.—Wagner calls attention to a condition of which only a comparatively small number of instances have been reported, where an exudation of serum takes place into all the large serous cavities of the body, without any apparent underlying cause. The disease is usually chronic, and ends fatally after a longer or shorter period. In the serous cavities we find all the evidences of a productive inflammation—adhesions between the pleura, accumulation of large quantities of fluid and masses of fibrin in the peritoneum, obliteration of the pericardial cavity with its consequences. Only a few instances of this disease have been observed during the early stages, among them a case reported by Wagner, where the serous exudate appeared simultaneously in all the serous cavities, and where a cure resulted in a relatively short time. The patient, a young man, was in good general health, and no cause for the appearance of the trouble could be ascertained. It is probable that the disease may have been caused by the presence in the circulating blood of some infectious material similar to what we find in acute articular rheumatism. The liver also became enlarged, and traces of biliary coloring matter appeared in the urine, so that this organ may have been the center of some of the circulatory disturbance. The only treatment applied consisted of the use of the ice bag in the cardiac region, rest in bed, and a light restricted mixed diet.

Deutsche medizinische Wochenschrift, March 14, 1907.

Hydrotherapy During the Climacteric.— Zweig discusses the value of hydriatic procedures on the nervous and vasomotor disturbances associated with this condition. The employment of these measures has met with insufficient attention, although there is abundant proof at hand to show that the improvement in the subjective symptoms may be well marked. Just what the effect is on the objective features it is difficult to estimate, because the individual effects vary to such a great extent. Extreme care must be used, however, in applying hydriatic measures because of the increased sensitiveness of the patient to external irritants. The temperature of the water should be such as to cause no reaction or only a slight one. In most cases a lukewarm bath, followed by the addition of cold water, may be taken two or three times during the course of the week. Salt may be added to the bath with benefit, but carbonic acid and electric baths may with advantage be omitted. The method referred to applies only to cases where the disturbance is a functional one. Where organic disease is present modifications must be considered. A number of cases are reported in which hydrotherapeutic measures were used with success. A feature of these was a loss in weight, which the author does not consider unfavorable because a woman is apt to become stout naturally during this period.

Experience with Oil of Chenopodium in the Treatment of Ascaris in Children.—Brüning has subjected the American oil to tests in a series of twenty cases and found that it is very efficient in the treatment of the condition noted. Depending on the age of the child, the dose varies from 8-15 drops three times daily, followed by a cathartic. It seems that one treatment is sufficient for most cases. The worms are apparently not killed by the oil, but merely narcotized, so that the administration of the cathartic is most important. The author believes that the efficient action of the remedy resides in an ethereal oil of the following composition: $C_{10}H_{16}O_2$. Experiments have shown that the same effect may be obtained with the latter as with the ordinary oil.

Action of Baths of White and Blue Light Upon the Blood.—U. Masucci records experiments to ascertain the effect of baths of blue and white light on the blood. His conclusions are given us thus: White light produces a slight increase of red corpuscles and diminution of white corpuscles. There is an increase of lymphocytes, and slight increase of nongrannlar mononucleated cells, and a slight diminution of polynucleated and eosinophiles. The changes in eosinophiles are most permanent. The effects are due to negative phototrophismus, which has a repulsive action on the polynucleated cells. There is a large increase of young cells, lymphocytes and mononucleated. Blue light produces a still greater lessening of leucocytes. The effects are more marked and more transient on all the forms of cells. Only the diminution of eosinophiles is permanent. These changes are due to the chemical rays. Phototrophismus acts on the lymphoid tissue of the bone marrow, driving the polynucleated cells from the circulation to the spleen. The increase of lymphocytes is due to the effect of the rays on the glandular lymphoid tissues, which makes the lymphatic circulation more rapid. There is a renewal of young cells and a destruction of the old ones.—*Giornale di Elettricita Medica.*

Book Reviews.

SYLLABUS OF LECTURES ON HUMAN EMBRYOLOGY. An Introduction to the Study of Obstetrics and Gynecology for Medical Students and Practitioners; with a Glossary of Embryological Terms. By WALTER PORTER MANTON, M.D., Professor of Clinical Gynecology and Professor Adjunct of Obstetrics in the Detroit College of Medicine; Fellow of the Zoölogical Society of London, of the Michigan Academy of Sciences, etc., etc. Third Edition. Revised and Enlarged. Illustrated with numerous outline drawings. Philadelphia: F. A. Davis Company. 1906.

THE essentials of embryology are here set forth in condensed form primarily for the use of students, but more advanced readers who may wish to refresh their memories or to learn the present standpoint of workers in this difficult subject will no doubt find it equally useful. It is clearly written and fairly well illustrated, and seems well adapted to its purpose.

TEXTBOOK OF ANATOMY FOR NURSES. By ELIZABETH R. BUNDY, M.D., Member of the Medical Staff of the Woman's Hospital of Philadelphia; Gynecologist, New Jersey Training School, Vineland; Late Adjunct Professor of Anatomy and Demonstrator of Anatomy in the Woman's Medical College of Pennsylvania; Formerly Superintendent of the Connecticut Training School for Nurses, New Haven. Philadelphia: P. Blakiston's Son & Co., 1906.

IN this well constructed book the trained nurse will find all that is essential for her to know of the anatomy of the human body. The descriptions are clear and concise, and the work is judiciously illustrated with upward of 200 well executed pictures, a number of them in colors. The book is well conceived and well executed and will be found most useful to those for whom it is intended.

SURGERY. ITS PRINCIPLES AND PRACTICE. By various authors. Edited by WILLIAM WILLIAMS KEEN, M.D., LL.D., Professor of the Principles of Surgery and of Clinical Surgery, Jefferson Medical College, Philadelphia. Volume I. Philadelphia and London: W. B. Saunders Company. 1906.

UNDER the skilful direction of the accomplished editor the contributors to the first volume of this extensive work have produced a series of essays that promise well for the volumes that are to follow. The present volume is devoted to the customary introductory and general subjects. The chapters on surgical physiology, and wounds and contusions by Dr. Geo. W. Crile contain many practical applications of experimental data obtained by the author, among which the discussion of the nature and treatment of shock and collapse are prominent. A section is devoted to the subject of blood pressure determinations and their practical value in surgery. Infection and immunity have been made the subject of a chapter by Dr. Ludwig Hektoen in which the involved ramifications of these difficult branches of modern research are set forth in simple but adequate fashion, and Dr. J. George Adami contributes an article on inflammation in which the author's well-known views as to the conservative nature of this process are detailed. A chapter of especial interest, not only to the surgeon on account of the many practical considerations involved, but also to the pathologist, owing to the large amount of original research it represents, is that on the processes of repair by Dr. F. C. Wood. Concerning the introductory essay on the history of surgery by Dr. James G. Mumford, one can but echo the writer's regret that the exigencies of space did not permit its extension to a greater length. Indeed, the need of brevity seems to have led him to omit mention of much of value that has been accomplished by American surgeons, especially those of the Southern States. The other articles of the volume are by Drs. John Bland-Sutton, John C. Da Costa, John C. Da Costa, Jr., Charles H. Frazier, Leonard Freeman, Edward Martin, Edward H. Nichols, and Eugene A. Smith.

In spite of the natural defects inherent to systematic treatises that are written by many hands, this form of mosaic work appears to be gaining in popularity, no doubt deservedly so, for with the ever-increasing scope of medical and surgical knowledge there can be but few men in a generation whose leisure and experience would enable them to produce a sufficiently comprehensive and authoritative guide for general use. The present work is, of course, by no means free from faults: some articles must inevitably fall below the average in excellence and some overlapping and some omissions are sure to occur in spite of the most careful editorial supervision. The publishers have done their part to give the subject matter an appropriate setting: the type is clear and the illustrations are excellent. Their beauty has been gained, however, at the expense of the reader's comfort, for the highly calendered paper used which lends itself so well to half-tone reproduction is also, at least by artificial light, very trying to the eyes. The binding also is badly done, which is a serious defect in a work that presumably is intended to withstand the wear and tear of frequent reference during a period of years.

PRACTICAL MATERIA MEDICA FOR NURSES, with an Appendix Containing Poisons and Their Antidotes, with Poison-Emergencies; Mineral Waters; Weights and Measures; Dose-List, and a Glossary of the Terms Used in Materia Medica and Therapeutics. By EMILY A. M. STONEY, Graduate of the Training-School for Nurses, Lawrence, Mass.; Late Head Nurse, Mercy Hospital, Chicago, Ill.; Late Superintendent of Training-School for Nurses, Carney Hospital, South Boston, Mass.; Author of "Practical Points in Nursing." Third Edition. Thoroughly Revised. Philadelphia and London: W. B. Saunders Company, 1906.

THIS is a well written, intelligently condensed handbook of materia medica adapted to the needs of nurses and others who would familiarize themselves with the properties and doses of the drugs most commonly employed to-day in medical practice. The subjects are taken up in alphabetical order and not according to therapeutic uses, but their classification is presented in a table in the introduction. A list of poisons and their antidotes, a dose-table, a glossary of unfamiliar terms, and an index complete the work. The book should be in every nurse's library.

ELEMENTARY MANUAL OF REGIONAL TOPOGRAPHICAL DERMATOLOGY. By R. SABOURAUD, Director of the City of Paris Dermatological Laboratory, St. Louis Hospital. English Translation by C. F. MARSHALL, Late Assistant Surgeon to the Hospital for Diseases of the Skin, Blackfriars, London. New York: Rebman Company; London: Rebman, Limited, 1906.

FOR the general practitioner, who sometimes has occasion to treat skin diseases, this is probably the most useful volume published. Its great and peculiar value is as a first aid in diagnosis. The different regions of the skin are taken up one by one, and the eruptions that occur on each are described in fair detail. A novice, in doubt as to the lesion before him, gets little help from the ordinary textbook, for he does not know where to turn, but with this volume he finds quickly a clear description of the various diseases that may occur upon the area involved, and then, if necessary, he may seek fuller information elsewhere. The translation is generally very good; only occasionally has the language been injured in transit, as when the phrase "seconde enfance" is rendered by second infancy, whereas the French locution means simply childhood, and has no reference to dotage. A graver fault is the inaccuracy with which the formulas are transcribed. Generally they approximate sufficiently to the original, but occasionally, and probably through careless proofreading, the proportions are made to differ radically in the French and the English versions. There are slight condensations in the text, but without any sacrifice of clearness. The presswork is good, the illustrations are still as clear as in the original, the book is lighter and easier to handle. On the whole, it is an exceedingly valuable work, and if its prescriptions are accepted with caution, it is a very sound guide.

THE NATURE, CAUSES, VARIETY, AND TREATMENT OF BODILY DEFORMITIES: In a Series of Lectures delivered at the City Orthopedic Hospital in the year 1852, and subsequently, by the late E. J. CHANCE, F.R.C.S. Eng. With illustrations drawn on wood by the Author from cases in his own practice, and many additional drawings and copious notes from cases in the Editor's practice. Edited by JOHN POLAND, F.R.C.S. Eng. Second Edition. In two volumes: Vol. I. London: Smith, Elder & Co., 1905.

THIS volume consists of six lectures delivered more than half a century ago. Its value, therefore, is chiefly historical; and the student of that side of medicine will find in the introduction and notes several interesting points. Thus, the rise of special practice and of special hospitals, and the criticism and opposition evoked thereby; how men like Cheselden and Abernethy sent cases of club-foot to bonesetters for treatment; how the terms specialist and quack were once synonymous—all these make interesting reading. It is also noticeable that the lectures of fifty years ago were characterized by fine literary style, broad general culture, abundant knowledge of the subject under discussion, and were evidently prepared with the most painstaking care; on all of which points they more than hold their own with similar publications of later date.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held March 21, 1907.

THE PRESIDENT, DR. JOHN A. WYETH, IN THE CHAIR.

THIS meeting was held under the auspices of the Section on Genitourinary Diseases. The subject of discussion was "New Growths of the Bladder."

Pathology.—Dr. F. S. MANDLEBAUM opened the symposium with a paper which was based chiefly on the observation and study of specimens referred to the Pathological Department of the Mount Sinai Hospital during the past nine years, and embraced twenty-nine cases of primary tumor of the bladder and eight of secondary tumor. Among these thirty-seven cases were two, inoperable in nature, in which the specimens were obtained at autopsy. The remaining thirty-five cases were operated on by the attending staff. The most satisfactory classification of these tumors was (1) epithelial tissue group, in which were placed papilloma, adenoma, carcinoma, and cysts; (2) connective tissue group, comprising fibroma, myxoma and sarcoma; (3) a muscle tissue group, in which were placed myomata. Statistics showed that primary bladder tumors comprised about 0.7 per cent. of all tumors, and were quite equally divided between males and females. Carcinoma as a rule was found between the ages of fifty and sixty, while sarcoma occurred more frequently in younger subjects. The benign tumors might arise at any period. Chronic irritation was an important factor in the etiology. Calculi, cystitis, the *Distoma hematobium*, the irritating effects on the bladder in the manufacture of aniline dyes, as well as psorosperms, had all been noted as being of etiological significance. Secondary tumors were those arising in neighboring or adjacent organs and growing into the bladder by direct extension. These tumors frequently originated in the prostate, uterus, vagina, or intestine. Metastatic bladder tumors were of the greatest rarity. Dr. Mandlebaum took up the consideration of the tumors of the different types, illustrating each with photomicrographs. He believed that a better name for papilloma was fibroepithelioma, inasmuch as both of these structures were involved in its production, or better still, papillary fibroepithelioma. A papilloma might occur singly or be multiple, and might arise from any portion of the bladder wall. The typical form consisted of a stem or pedicle, springing directly from the mucosa. Many tufts or villi sprang from the pedicle, giving a shaggy appearance to the growth. The villi usually bifurcated into innumerable branches, varying somewhat in length. Occasionally a deposit of phosphates might form superficially. A papilloma might range in size from a small tumor of a few millimeters in diameter to one nearly filling the bladder. As in all other tumors of this organ, the growth might interfere with the normal bladder functions, so that urination might be disturbed or hydronephrosis be produced, depending upon its situation. Inflammation might supervene and the tumor become involved in the inflammatory process. The tendency for papilloma to recur after removal was a well established fact. The growth frequently reappeared as a simple benign tumor, though in some instances it might be distinctly malignant in character. Can a simple, benign papilloma become malignant? The weight of evidence to-day was confirmative, and cases had been described which seemed to bear out such a view. In one of his cases the change in the epithelioma from simple papilloma to carcinoma was most striking, and the transition could be clearly followed. The statistics of several carefully examined series showed that the simple papilloma formed about twenty per cent. of the cases of primary bladder tumors. A papillary carcinoma might resemble the simple papilloma so closely that a microscopical examination alone could decide. In his series this variety of tumor occurred in sixteen of the cases, or fifty-seven per cent. of all the primary growths. All the cases were in males, and the ages ranged from twenty-five to eighty-two years, the average being fifty-two. In all the bladder wall was infiltrated; in three no involvement had occurred, and in two it was impossible to determine this point. Ulceration and hemorrhage were not infrequent. A papillary carcinoma might arise from any portion of the bladder. The prostate was not involved in any of his cases. Perforation of the bladder wall was very rare, and metastases occurred only in the late stages. The non-papillary forms of carcinoma were somewhat less frequent. The flat or squamous celled carcinoma might be found in the bladder, but also was somewhat infrequent. In his series it occurred only in two cases, both males. There were five cases of fibrocarcinoma, all in males, in his series of cases, and, in every instance, the bladder was infiltrated, and all terminated fatally. These five cases were all carefully examined before operation, they were diagnosed as new growths of the bladder, and as such were operated upon. A close study of all the extirpated tumors, and a post-mortem examination in two of the cases, revealed the fact that four of these tumors were primary growths of the prostate, with a secondary involvement of the bladder. Therefore, he was compelled to place four of these five cases in the class with the secondary tumors. A similar observation was made in studying two cases of adenocarcinoma, both in males, aged, respectively, forty-eight and sixty-seven years. In both the prostate was primarily affected. Simple adenoma, as well as fibroadenoma, was quite rare in the bladder. Colloid carcinoma was not common in the bladder. Cysts might be found as the result of congenital defects connected with the urachus, the Wolffian body, or Gärtner's duct. The connective tissue tumors were less frequent than those already described. Fibroma was not often met. The favorite site was at the base of the bladder, and was described as a hard growth, often pedunculated, and containing fibrous tissue and muscle fibers. Myxoma was not so rare a form and occurred in childhood often. Other forms of sarcoma other than myxosarcoma might be found in the bladder, but as a rule they did not have any definite or uniform features. They were sessile as a rule, but a pedunculated variety had been described. It was interesting that about thirty per cent. of the reported cases of sarcoma had been found in females. Myoma of the bladder was not common. Only one case of dermoid of the bladder was known, that described by Thompson.

Diagnosis.—Dr. HUGH CABOT of Boston read this paper. He said the diagnosis of bladder tumors was not as satisfactory as it might be. The failures in early diagnosis were responsible for the failures in the treatment. Failure to take advantage of the new methods now was a serious responsibility. The real dangers from delay were: (1) Continued growth of the tumor; (2) infection of the bladder; (3) infection of the upper urinary tract, and (4) damage or destruction of one kidney by pressure upon the lower end of the ureter. An early diagnosis might be the means of avoiding these dangers. It still remained that the average practitioner would allow a painless hematuria pass by undiagnosed. The cardinal symptoms of tumor of the bladder were a painless hematuria and disturbance of bladder function. The hematuria must be distinguished from disease of the kidney, ureter, prostate, and other diseases of the bladder other than tumor. There was great difficulty in diagnosing disturbances of bladder function. Tumors of the bladder must be differentiated from stone, from hypertrophied prostate, etc. In attempting to differentiate bladder tumors from disease of the prostate, there was a lack of symptoms absolutely diagnostic. There were many suggestive symptoms to bear in mind in connection with tumors of the bladder. Tumors often existed for a long time without exact symptoms. Hematuria was the first symptom in

one-half the cases, and it was always present at some stage of the disease, but was not an early symptom. On the other hand, a profuse and even fatal hemorrhage might occur even from small growths. Hematuria was almost always followed by the stage of infection. In some cases the surface of the growth was crusted with calcium salts. The symptoms were not at all diagnostic. There were two methods of examination of value and which would lead to a correct diagnosis, examination by the rectum, and the use of the cystoscope. Dr. Cabot told of a colleague of his who attempted to crush a stone. Upon opening the bladder a fibromyxoma was found. The only thorough diagnostic method at hand now he believed to be the cystoscope. In some cases the bleeding might be so profuse as to preclude its use; then one should do a suprapubic cystotomy. Some time was spent in speaking of the difficulties of cystoscopy. It was the duty of all practitioners in the presence of a painless hematuria, or hemorrhage accompanied by pain, or cases of disturbances of bladder function, to make use of the cystoscope by promptly referring the case to one who could use one. Nothing was gained by delay.

Treatment.—Dr. Ramon Guiteras presented this communication. He said before considering the treatment of bladder tumors, one must take into consideration the different varieties of tumors, their size, shape, and location, the symptoms they produce, the complications that existed or might develop, the age and general condition of the patient, etc. Finally, after studying the individual case carefully, and considering the different factors connected with it judiciously, one should make up his mind whether or not the patient should be operated upon; for it must be remembered that patients with bladder tumors often lived many years in comfort without operation who, if they were operated upon too radically, might not survive the operation. So soon as hemorrhage occurred in bladder tumor treatment should be begun by rest in bed and a bland diet, 5 to 15 grains of calcium every two or three hours, tincture of iron, ergot, and gelatin. Locally a catheter should be introduced and an attempt made to aspirate or suck out any blood clots. If none come away by aspiration, a small quantity of hot saline solution should be introduced into the bladder, and the catheter worked about carefully in an effort to break up the blood clots without causing additional hemorrhage. Gelatin might be used locally. Dr. Guiteras said he had never performed suprapubic cystotomy, and he packed the bladder in cases of hemorrhage due to tumors. Tenesmus and spasm were treated palliatively by antispasmodics, massage of the prostate, if associated with prostate trouble, and stretching the bladder sphincter with a Kohlman dilator. In cases of bladder infection it should be washed out with solutions of boracic acid, permanganate of potassium, or nitrate of silver followed by a solution of organic silver. The operative treatment of vesical tumors consisted in removal through the dilated urethra in women, vaginal vesical incision, perineal cystotomy (Thompson), removal by means of the cystoscope intravesical (Nitze), suprapubic cystotomy, cystectomy (resection), cystectomy complete (extirpation), and nephrotomy-nephrostomy. After considering each of these methods he concluded (1) that more attention should be paid by cystoscopists to the intravesical work by means of the Nitze's operating cystoscope in the radical treatment of tumors of the bladder, as it was to-day beginning to occupy the same position in tumor work that the lithotrite had in the work on vesical calculi. (2) That more attention should also be given to the use of the air cystoscope for increasing its usefulness in the treatment of bladder disease. (3) That in the case of all tumors in the front and sides of the bladder, in which there was plenty of space to make the incision clear of the tumor base, excision was the best operation. (4) That nephrostomy would in the future be as important an operation in cases of malignant tumors of the bladder as colostomy was at present in cases of malignant disease of the rectum. (5) That malignant tumors of the rectum situated about the mouths of the ureters should not be excised, nor should the bladder in these cases be extirpated, but when through the pressure of the growth on the ureters of one side, the kidney on that side began to develop a renal retention, a nephrostomy should be performed. (6) That in the treatment of bladder tumors they should be conservative and not too radical in their operative procedures. Casper said "patients generally do better and live longer without than with operation." Dr. Guiteras was inclined to believe that he was right in malignant cases.

Results of Surgical Treatment.—Dr. F. S. Watson of Boston presented four tables showing the operative results of tumors of the bladder. There was an extraordinary tendency, he said, to malignant transition. The malignant process might begin in the minute villi in the periphery. There might be recurrences not *in situ*, but elsewhere in the bladder. There were two facts to be considered in connection with operative results, and they both had to do with the cause of death. There were an extraordinary number of recurrences in benign tumors; this was a fact in connection with operations of partial resection involving the transplantation of one ureter in the rectum, skin, or elsewhere; also in all cases of double transplantation necessitated by a total extirpation; the deaths in these cases were due, one-half to the shock produced, the other to an ascending infection. One or two things might be done. The growth might be bitten off and then let alone. He advised against touching the malignant growths at all. That was all right in small polypoid growths. He asked how these unfortunate results could be improved upon. He could conceive of but one way. If such a large number of benign tumors of the bladder become malignant, it seemed to him that they should treat all cases as though they were malignant tumors, and treat them by as radical measures as could be applied, namely, by taking away the diseased area, performing a total extirpation. The question then arose, why so great a mortality? If one could diminish the length of time of operation and could cut off the deaths occurring from an ascending infection, the patients would have a fair chance. He advised a double bilateral simultaneous nephrostomy done as a preliminary step. Then after a month or six weeks removal of the bladder as well as of the prostate and seminal vesicles if there was any question of their being involved. One shortened the time of operation by getting rid of the ureteral implantation. Cases of recurrent benign tumors of the bladder, or recurrences following tumors originally benign in which there was some doubt that they might be carcinoma, called for this method of operating: Dr. Watson employed it in all cases in which it was proper to do a radical operation, as though it was a carcinoma from the start. He never operated in this way upon sarcomata; they never got well. In three cases of bilateral simultaneous lumbar nephrostomy there was no shock *per se*. One died from a continuance of the uremic condition. Were they not going to have trouble with infection of the kidney? He answered no, that the kidneys would drain freely if they were kept clean. Was there not an intolerable distress when a double nephrostomy was done? He said no, that he had a patient who had been draining for twelve years, in perfect health, and with not a smell or odor. Nobody was aware of his condition. Dr. Watson wished to have it repeated and emphasized, that there was no shock *per se* in doing a double lumbar nephrostomy simultaneously. The shock would be greatly reduced by a total extirpation by first having the whole question of urinary drainage settled at a preliminary operation, having the secretion properly diverted.

Dr. Howard Lilienthal referred to that part of Dr. Mandlebaum's paper in which he said that malignant

growths of the bladder starting in the prostate might be mistaken for primary growths. In other words, in secondary malignant growths of the bladder 80 per cent. gave chances that the parent growth was in the prostate. With regard to the cystoscope, one could not be dead sure of what they saw through it; but one could be sure when working through a suprapubic incision. He said that instead of making a hole in the perineum or introducing a cystoscope, it would be better to make this suprapubic opening. As to Dr. Watson's suggestion, he was convinced that the procedure was the most rational treatment for cancerous disease of the bladder with one possible exception. He thought they should first make the suprapubic opening and obtain a piece of the growth for diagnostic purposes, and then subsequently doing the double nephrostomy. This would greatly diminish the dangers. There was no question but that by this operation they diminished the dangers of an ascending infection. The ureters should be implanted into an excluded loop of intestine, preferably the ascending colon previously excluded.

Dr. H. Goldenberg said that at the Mount Sinai Hospital during the last year they had twenty-one cases of bladder tumor, with thirteen operations, the remaining eight refusing operation, or else being inoperable. Of these thirteen cases, eight were carcinomata, four papillomata, and one sarcoma. The results were bad in carcinoma when there was infiltration. The time was as yet too short to report the results in papilloma. The question arose as to whether they should operate upon these cases so soon as the diagnosis was made; it was difficult to answer. He had had a case which he had watched for four years, a case of benign tumor of the bladder, with intermittent hematuria. He had had another opportunity of watching one of Casper's cases in Berlin which had been under observation for eleven years, the patient having refused operation. One should be governed by general surgical principles in these cases.

Dr. Edward L. Keyes, Jr., spoke in reference to palliative hemostasis where operation was refused or where it was impossible to do operation, when at times the bleeding was quite sharp, and said that he had found out one or two tricks which he believed would be worth while mentioning. Of the internal remedies, especially when there was bleeding from the kidneys or the bladder, he believed the best to be turpentine, given in capsules, 10 minims three times a day, or 10 minims given on a lump of sugar. Another remedy he favored was the fluid extract of senecio aureus given in dram doses three times a day. As a local hemostatic he believed the best remedy was alum, and the form that he used was Squibb's camphorated alum; a dram of this was added to eight ounces of warm water and injected into the bladder. This was far better than adrenalin.

Dr. Eugene Fuller said that in some cases there was a tendency to diagnose a granulomatous condition met with at the base of the bladder as tumor of the bladder. If that was removed or scraped off, the patient would gradually get well. These should not be classed, however, as bladder tumors. If there was a malignant growth of the bladder he thought it better to leave it alone, or do a nephrostomy. Partial resection was not worthy a trial.

Dr. H. H. Morton of Brooklyn called attention to the importance of diagnosis as a prognostic aid, especially the knowledge whether the tumor was benign or malignant. In the early stages one could see with the cystoscope the tumor floating, but when there was bleeding this instrument threw no light upon it, even when adrenalin was used. If it were possible to take a piece with the Casper or Nitze's cystoscope for microscopical examination, then they would have something to go on. One could not tell whether the tumor was benign or malignant merely by looking at it. He had seen the operating cystoscope used by Nitze, and it was a very difficult instrument to manipulate.

Dr. Harlow Brooks spoke of the prevention of malignant disease of the bladder and said that a great many cases of vesical carcinoma originated in the prostate; therefore, to prevent them closer inspection and observation of conditions in the prostate should be called for.

Dr. L. Bolton Bangs, speaking in reference to the double nephrostomy, asked, "What is the use?" Patients who required such an undertaking as that had already reached such a point in their malady that it was utterly hopeless, for metastases had already taken place. The degree with which the disease had extended from the bladder was an utterly unknown quantity. The disease was beyond you. The question of nephrostomy which Dr. Watson proposed appealed strongly to him, but only in a very limited class of cases. The question of shock did not concern them. Dr. Bangs said that he had a patient who had been carrying a tube for eleven years in the loins. Before undertaking a double nephrostomy the extent of the malady should be determined as far as was possible.

Dr. George E. Brewer said that he had a patient who had had a double nephrostomy performed on him three years ago; it was done for suppurative disease of both kidneys from calculi. The man was in good condition and not inconvenienced at all.

Reform Urged in the Board of Health Inspectors.—Dr. A. Jacobi introduced the following resolution, which was unanimously carried, proposed to the consideration of the Academy by the Section on Public Health: *Resolved*, That the New York Academy of Medicine urge upon the Department of Health of New York City the following requirement, namely, that the inspectors of the Department of Health observe the same precautions as to clothing and personal disinfection, when their duties bring them into contact with communicable diseases, as are required by the physicians in attendance at the Willard Parker Hospital.

The Milk Supply of New York City.—Dr. Jacobi also introduced a resolution on this subject (see page 527).

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, March 18, 1907.

The Corresponding Secretary, Dr. Frank C. Raynor, in the Chair.

The Executive Council announced that on account of the continued illness of the late Treasurer, Dr. J. Lee Morrill, Dr. A. Ernest Gallant had been appointed to that office.

Weak Foot and Its Treatment.—By Dr. Carl R. Kepler. Under this head, the author included: (1) The nondeforming, painful weak foot; (2) the deforming weak foot, without spasm; (3) the spastic deforming weak foot or flat foot. Before taking up the treatment of this condition, which he regarded as the most common of all painful deforming processes the human body was subjected to, he stated that hand in hand with the trend of civilization had developed the distorting and so-called stylishly beautifying feature of our footwear, and the shoemaker was confronted with the necessity of either building the same according to popular fancy, or losing his business. The resultant misshapen leather boxes into which people now squeezed their feet were of so many varieties that it was impossible to describe them, and he emphasized the fact that these shoes were one of the main causative factors in the development of adult weak foot. As a prophylactic and curative measure he mentioned, 1. Correct shoes: In the incipient stage, when only indefinite pain and weakness were complained of, and before any deformity or stiffness had developed, a well built shoe, combined with graded, corrective exercises, was usually sufficient to overcome the affliction. A high lace boot was ordered, reaching up to and including the ankle, not because the constriction of the latter was a necessary adjunct to efficiency, but because it seemed

to be the only kind of footwear that would fit snugly, hold the foot evenly, and retain its shape. 2. Correction: Before fitting any corrective brace, and also after its application, it was of the utmost importance to bring the general tone of the foot structure, as well as of the muscles and tissues, into as nearly a normal condition as possible, thus to retain them and actively aid in reducing the deformity itself. To achieve this, he employed active exercises, such as adduction and dorsiflexion; rising on the toes, and board walking. As further aids, he employed manipulation, both manual and mechanical. Complications had to be met and treated as they arose. Massage, electricity, and vibration were valuable aids in overcoming muscular weakness and circulatory disturbance. Other adjuncts that he had found of value in certain cases were hot foot baths, medication, retention, built-up shoes, adhesive plaster dressing, and braces. Of the latter there were legion, but the salient feature of the brace was to train the act of walking and force the foot structure continually into its normal attitude, as well as to overcome the apparent deformity. In certain severe and selected cases, operation was justifiable, but as a general rule he deemed it advisable to try less radical means before resorting to it. In the advanced type of flat foot, in which correction of the deformity either actively or passively was impossible on account of the absolute rigidity and marked tenderness, the administration of an anesthetic was indicated. Dr. Keppler said that while the treatment he had outlined in his paper was long and tedious, unhappily a deformity was not a diseased spot which we could cut away. It had to be slowly and gradually overcome. As there were no two normal feet alike, so there were no two misshapen feet alike, and individual, careful treatment was therefore of prime importance.

Results in the Treatment of Congenital Dislocation of the Hip by the Bloodless Method.—Dr. Dexter D. Ashley stated that after the flood tide of popular enthusiasm following the memorable visit of Dr. Lorenz to this country four years ago, which imparted a marked stimulus to the work of the orthopedic surgeon in general and to the study of the congenitally dislocated hip in particular, a strong ebb tide soon set in, due to disappointments of various kinds, and enhanced by the overexpectations of profession and laity, through a lack of understanding of the limits of the operation in varied hands, and of the long and careful after-treatment that was necessary, to which might be attributed many failures to obtain good functional results. During the past three years, however, the operation had regained ground in America, more operators appreciating its application and limitations, and reporting increasingly favorable results. Dr. Ashley said that while we should not conclude that this was the only method to be used in all instances, recent statistics had raised the percentage of successes over those quoted by Lorenz and his followers in 1902. This was principally due to the acceptance of good functional results, instead of considering as cures only those anatomically perfect. It was, of course, impossible to have an anatomically perfect hip where there was deformity of the head, or a coxa vara or valga, even if the deformed head was placed within the acetabulum. A careful study and record of conditions found in each case before operation would help to eliminate those to which the method was inapplicable, and would reduce the failures from the operation to a negligible quantity. Where chances were taken which were not authorized by the limitations of the operation, the results should not enter into statistics of those cases to which the operation was generally considered applicable. After quoting the statistics recently collected by Dr. W. G. Stern of Cleveland, Dr. Ashley said he had operated seventy-nine times for congenital dislocation of the hip by the bloodless method, with the following results: In twenty-nine an anatomical reposition was obtained; in twenty-five there were good functional results, and nineteen were improved. There were six failures, although two of these considered themselves very much improved. Five of the six failures were beyond the age limit, and the sixth was one of his early cases. Of the seventy-four cases suitable for statistics, many were beyond the age of selection, which was from three to five years. Some had been previously operated upon, thus reducing very materially the possibilities of success when the first operator did not succeed in making an anatomical reposition. Many of the patients were poor, and the parents were negligent in regard to bringing the children for after-treatment or supplying them with modified shoes. Others resided at a distance, and were so situated financially as to make careful observation impossible at the critical stage of the treatment. In spite of these adverse conditions, he had succeeded in getting 73 per cent. of very good functional results, the patients walking with a scarcely perceptible limp, and 98 per cent. of functional improvement. While perfection was not attained by this method, yet he contended that the results were better, on an average, than with the open operation, while danger to life during the age of selection was almost *nil*. In connection with his paper, Dr. Ashley showed a number of patients upon whom he had operated, together with a series of skiagraphs.

Affections of the Sacroiliac Joints.—Dr. Henry Ling Taylor, who presented this paper, said it was strange that one of the largest and most important joints in the body had attracted but little attention either from anatomists or surgeons. Standard anatomical works were brief and unsatisfactory in their descriptions of the form and function of these parts, and even the more elaborate treatises differed among themselves as to the size and location and even the existence of a synovial cavity, and still more as to the existence of motion under normal conditions, many classing the joints at the sides of the sacrum as fixed, others as movable or slightly movable. This was no doubt due in part to the variations presented by different subjects and at various ages. It seemed to be true that these joints varied in structure in different individuals and under different conditions rather more than most joints. Obstetricians had been for a long time interested in the structure and function of the pelvic joints, and had recognized the considerable degree of mobility which supervened in these parts during pregnancy. This occasionally was of such extent as to give rise to extreme disability and entire loss of locomotion in the late months of pregnancy or after delivery. It frequently occasioned pains and less serious interferences with locomotion whose cause was often unrecognized. The increased mobility at the iliac joint in parturient women permitted a pubic separation of several centimeters after symphyseotomy, and this was seldom followed by permanent disability. When the pubic separation amounted to five to seven centimeters, the ligaments in front of the iliac joints were partially peeled off with the periosteum, and partially ruptured. The pubic joint, the joints of the spine, and probably all the joints of the body participated in this puerperal relaxation. Infections of the iliac joints after parturition had also been reported, and this was briefly the state of our knowledge when Goldthwait and Osgood of Boston published their paper on the pelvic articulations in the *Boston Medical and Surgical Journal* (May 25 and June 1, 1905), in which they showed from anatomical investigation and clinical observation that the iliac joints were normally movable in men and women, and that they were subject to relaxation, strains, displacements, and infections; in short, to the affections of which the larger joints were subject. The diagnosis of iliac affections from disease of the hip joint was easy, as with the latter motion at the hip was more or less restricted; in iliac disease this was not the case, excepting when the thigh was flexed with a straight knee. In primary sciatica there was pain in the sciatic distribution, and tenderness over the nerve trunk; in iliac affections there was tenderness over the iliac joint, and

usually none over the sciatic. In sciatica, raising the extended leg would cause pain in the sciatic rather than in the iliac joint, and raising the leg of the unaffected side would not cause pain, although it often did in iliac affections. This maneuver might also cause pain in the lower back in rheumatoid and other affections of the lumbar spine. Here the possibility of a complicating iliac affection should be borne in mind, and the occasional occurrence of sacral disease should not be forgotten. The prognosis was good in a considerable proportion of cases under proper treatment. A certain few were fairly obstinate, and could be only partially relieved. The treatment for laxity, irritation, or inflammation was pelvic strapping with two-inch adhesive plaster just above the trochanters, as an emergency measure; the adjustment of a pelvic belt or girdle, the use of a special corset reinforced by shaped steel bars, and provided with a pelvic belt, or a long plaster jacket or corset firmly grasping the pelvis. Recumbency was necessary in a few of the cases. All cases of obscure pains across the sacrum, in the sacroiliac region, behind the hip and down the legs, with more or less disability in standing, sitting, and lying, so frequent in gynecologic, neurologic, and general practice, should be carefully examined for affections of the iliac joints. If this was done, many obscure, tedious, and seemingly hopeless cases might be transferred from the list of incurable to that of curable affections.

Posture as an Aid in the Diagnosis of Bone Lesions, Before the Occurrence of Deformity.—By Dr. Reginald H. Sayre, with lantern illustrations. The speaker said it frequently happened that the child was brought to the orthopedic surgeon with the statement that it turned its toes in, and the request was made that it should be caused to turn its toes out. Investigation of these cases almost invariably showed that the pigeon-toes was a voluntary act on the part of the child, taken in an unconscious attempt to protect a weak arch from the strain of weight-bearing. Knock-knees not infrequently lay behind the pigeon-toes as a cause, the weight being brought in consequence of the knock-knees much more on the inner than on the outer border of the foot if held in the usual position, and the child turned in its toes because it was more comfortable in that position, and the surgeon who compelled it to turn its toes out without first remedying the knock-knees was doing more harm than good. This attitude of pigeon-toes, Dr. Sayre said, was typical of a number of so-called "bad habits" which were held responsible by parents for various deformities, whereas the truth was that the habit was only the expression of motion along the path of least resistance, the child assuming certain postures, or walking in a peculiar manner because certain abnormalities of structure rendered it easier to do this than to perform the motion in the usual way. The child was frequently scolded for doing what it could not help doing, and the underlying influence which produced the habit was not investigated. Children were scolded for being inattentive when the fact was that they were deaf. Efforts were made to correct a forward stoop of the shoulders by braces, when a myopia should have been relieved by properly adjusted glasses, and the speaker said he had seen the walk of Pott's disease caused by an effort to relieve the spine from injury ascribed to a desire to imitate the peculiar gait of a fat negro cook. When André in 1636 described orthopedic surgery as "the art of preventing and correcting deformities in children," he included a part of the subject that had frequently been neglected in spite of its importance. Almost all the acquired deformities of the body were the result of disease which had been present for long periods of time, and which would have been discernible to those who knew how to properly interpret the danger signals which nature hung out for our information. The marked deformities only occurred after long periods of time, and could usually be prevented if the cause which produced them was recognized early in the disease.

Dr. Fred H. Albee said that some time ago, in attempting to look up the minute anatomy of the sacroiliac joint or synchondrosis, he was much surprised to find such a marked disagreement among the most prominent anatomists and gynecologists as to its histology and macroscopic anatomy. Morris, for example, held that even the presence of synovial membrane at all was not constant, stating that he believed it more apt to be present in the female. Luschka believed that a small amount of synovial membrane was always present, and that it increased in size at the time of pregnancy. Cunningham believed that hyaline articular cartilage existed usually. Testut, the great French anatomist, mentioned certain folds of synovial membrane occurring here and there on the margins of fibrocartilage. Morris denied the existence of appreciable movement at this joint, while Williams and Kuttner claimed that movement always existed. Dr. Albee said that when we considered the mechanism of this articulation, there was no reason to wonder at the presence of movement, sprain, and other affections which large joints were subject to. He had proved to his own satisfaction that it was a true joint. At the Cornell Medical School he had dissected forty sacroiliac joints, and the results were briefly as follows: Synovial membrane was found in all cases; the synovial cavity was as constant in its size and relations as that of any other large joint; distinct movement was measured in every case excepting one, and in that instance the joint was ankylosed from an existing osteoarthritis. The thinness of the capsule on the internal pelvic aspect of this joint was of importance surgically, in that the joint, when infected, was so apt to drain into the pelvis, thus causing a pelvic peritonitis.

Dr. A. Ernest Gallant, in referring to the treatment of weak foot, said that as a pupil of Dr. John Ridlon he had always made use of intoeing in running and dancing. He said that last January he had a patient who suffered from pain in her limbs in the late stages of pregnancy, and during a forceps delivery the pubic joint was heard to crack. After delivery the patient suffered excruciating pain; there was inability to move the legs and the same crackling noise whenever she attempted to draw up her legs or change from side to side. All of these symptoms were immediately relieved on tightly strapping the pelvis. The soreness that patients sometimes complained of after operation, Dr. Gallant said, he relieved by massage and change of position as soon as the effects of the ether had passed off.

Dr. Franz J. A. Torek, in discussing Dr. Keppler's paper, said he thought the orthopedist could rightly consider it within his province to superintend the manufacture of lasts upon which shoes for normal as well as for weak or deformed feet could be properly and scientifically fitted. Such work would be regarded in the line of prophylactic treatment, and would in nowise lower the dignity of the profession.

The discussion was closed by Drs. Keppler and Sayre.

Chicago Medical and Chicago Laryngological and Otological Societies.

At a joint meeting of these societies, held March 20, 1907, Dr. E. Fletcher Ingals read a paper entitled "Relation Between Diseases of the Faucial Tonsils and Rheumatism." He drew the following deductions: (1) He had gradually fallen into error regarding the relation of tonsillitis and rheumatism, and that what had appeared to him merely casual was in fact due to an identical cause for the two in from thirteen per cent. to possibly twenty-nine per cent. of all cases of acute tonsillitis. (2) Forty-five per cent. of the cases of tonsillitis had a rheumatic history, but sixteen per cent. of other affections of the throat and chest also had a rheumatic history, so that not more than twenty-nine per cent. of the cases of acute tonsillitis could fairly be attributed in any way to the rheumatic poisons, and more than half of these were very doubtful. (3) Among

his patients only nineteen per cent. gave a history of previous attacks of articular rheumatism and eighteen per cent. a history of muscular pains that they ascribed to rheumatism. (4) Eight per cent. of the cases of acute tonsillitis were attended by, or immediately followed by, articular rheumatism; the same number claimed to have had muscular rheumatism, while in five per cent. the rheumatic attacks immediately preceded the angina. (5) There was not as yet sufficient evidence to prove that the tonsil was the only or even the chief portal of entrance for the rheumatic poison. Considering, however, that acute articular rheumatism represented a mild type of septic hematogenic infection of the joints, there was no reason why the tonsil with its notorious facility for infection with pyogenic germs should not, possibly even frequently, assume the rôle of an infected wound leading to septic consequences of a systemic nature. These septic conditions varied in degree and location, and rheumatism was perhaps one of the phenomena. (6) The evidence did not yet justify the belief that inflammation of the tonsil might prevent or take the place of an attack of rheumatism. (7) The statement that the acute beginning of muscular rheumatism was nearly always preceded by tonsillitis was not supported by the histories of his case, as in only two per cent. did muscular rheumatism follow tonsillitis. However, in six per cent. muscular pains that were called rheumatism attended the tonsillitis, although they may have been due to the fever attending the inflammation of the tonsil. Dr. James T. Campbell followed with a paper in which he discussed the relation between disease of the faucial tonsils and enlargement of the glands of the neck. Dr. Charles M. Robertson discussed the occurrence of tuberculous diseases of the tonsils. Dr. Joseph A. Capps referred to the type of cases with acute cervical adenitis that occurred, especially in children, with a sore throat. This combination of sore throat and adenitis was important (1) because the combination had in the last year been more prevalent than usual; and (2) because the etiology of these infections was interesting. He described in detail the clinical picture of such cases. Dr. Daniel N. Eisendrath said that cases of acute enlargement of the lymph nodes of the neck probably corresponded to some extent with those described by Pfeiffer in 1899 as glandular fever. In the cases which he had seen the enlargement of the lymph nodes was out of proportion to the height of the temperature. He cited a case. There had been eleven undoubted cases of primary tuberculosis of the tonsil reported, the majority of them having been verified by autopsies and by finding primary tuberculosis of the tonsil, in which there were no other tubercle bacilli found in the body. A surgeon in operating for tuberculous glands of the neck should also remove the tonsils and adenoids. As to the relation between appendicitis and tonsillitis scarcely a winter had passed during the last two or three years without surgeons having seen tonsillitis in children followed by typical attacks of appendicitis, so that clinically the association of the two diseases was quite well established. Dr. Robert H. Babcock said that in a very large percentage of cases the portal of entrance of infection was the tonsil. A large percentage of the cases he saw were instances of some form of heart disease, and nearly all which he had investigated, since his attention was drawn to the subject a good many years ago by the researches of Fritz Meyer, had shown either chronically diseased tonsils, or a history of previous sore throat, and many times a tonsillitis. The trend of investigation was to the effect that the old notion that acute articular rheumatism was a blood disease in the sense of its being due to some chemical irritant must be abandoned; in fact, it was a specific disease, and many observations had been made which go far to prove that the microorganism responsible for attacks of acute articular rheumatism of the classical type was the diplococcus rheumaticus. As to the importance played by follicular tonsillitis in the production of acute endocarditis, Dr. Babcock cited the case of a young man who developed malignant endocarditis from which he died. Autopsy substantiated the diagnosis which was made during life. Dr. Frank S. Churchill said that in children the pediatrician did not see an arthritis as the most common and frequent manifestation of rheumatism. He saw rather endocarditis. Other manifestations of rheumatism were the subcutaneous enlargements which Cheadle and other Englishmen spoke of frequently; also erythema and pleurisy. Some English writers spoke of attacks of appendicitis as a manifestation of rheumatism. The speaker then went on to say that in his opinion chorea was another manifestation of rheumatism. The subject was further discussed by Drs. Elmer L. Kenyon and William L. Ballenger. The latter said that his experience had shown him that to remove the atrium of infection we should remove the tonsils to the depth of the crypts, and the easiest and most certain way to do that was to take away the tonsil with its capsule.

Chicago Surgical Society.

At a meeting held March 1, 1907, Dr. Allan B Kanavel read a paper on "Surgical Intervention in Leontiasis Ossea." Up to the present time the feasibility of surgical intervention for the cure or palliation of leontiasis ossea had not been carefully considered. The analysis of the cases noted in the literature, with the report of one observed by himself, was made for the purpose of determining whether or not such intervention was justifiable. And in case of operation, of deciding to what extent it should be carried, and what were the probabilities of curative or palliative results. Thirty-five so-called typical cases have been recorded and a careful study made of nineteen skulls. The general division of the cases may be made into: 1. Isolated bones involved. 2. Hemihypertrophy of the face and skull. These cases are always most marked in the anterior portion. 3. Bilateral involvement of certain bones. 4. Involvement of the entire face and skull. In these cases the inferior maxilla was frequently uninvolved or not mentioned. In relation to cerebral compression it was noted that fourteen patients showed symptoms which could be attributed to cerebral compression, and in at least half of these operation would have been of benefit to the patients. Seventeen of the thirty-five cases showed involvement of the orbital cavities. The eyes were pushed out by the increasing bony deposit, and this proptosis practically always preceded evidences of optic neuritis, and there was every reason to believe that the blindness was due primarily to the encroachment upon the orbital cavities. Many of the patients lived for years after blindness intervened. After adding the bibliography, the reports of the cases, and the skulls, the article was summarized as follows: "(1) Operative procedures are justifiable in a certain proportion of the cases. (2) No well defined operation can be suggested as a curative measure. The pituitary body has been observed enlarged in only one case and there microscopical examination is lacking. Further careful examination should be made when opportunity presents itself. (3) Palliative operations should be done to relieve cerebral compression, and encroachment upon the orbital and nasal cavities. The indication for these procedures is clear; the diagnosis can be made, and relief from symptoms with the preservation of sight and mentality for years can be expected. (4) Obstruction of the blood supply and operations for cosmetic purposes may be considered. (5) The relationship between acromegaly, von Recklinghausens' disease and generalized trophic changes in bones on the one hand and so-called leontiasis ossea on the other cannot be stated at the present time, therefore the latter should not as yet be classified as a pathological entity, although its clinical individuality should be retained."

St. Louis Medical Society of Missouri.

At the weekly meeting, Saturday, February 16, Dr. John Green, Jr., reported that the first meeting of the Ophthalmic Section had been very successful. Of a total of twenty-five members twenty were present, and there were eight contributions to the program. Dr. Jesse S. Myer gave an interesting demonstration of esophagoscopy on a patient having stricture of the esophagus. He called attention to three principal uses of the esophagoscope, viz., diagnosis, removal of foreign bodies, and as a most valuable aid in treatment of strictures. He emphasized the point that the use of the esophagoscope was attended with no danger if the obturator was removed as soon as it had passed the cricoid cartilage, and if the instrument was passed further under direct scrutiny of the operator. Papers on medical education in America, Paris, London, Berlin, other German universities, and Vienna, were read by Drs. John Young Brown, C. G. Chaddock, Llewellyn Williamson, A. E. Meisenbach, W. C. Gaylor, and Louis Rassieur. Dr. Ravold, discussing the question of post-graduate study, said that America had a great deal to offer in facilities for medical education. After a student had finished the prescribed medical course and had spent one or two years in a hospital or with some good clinician, he was ready to look about to learn a specialty. America had splendid laboratories and just as great masters in charge as would be found anywhere. They would take one as far as they could and push him off into original research. We had the best surgeons the world has produced. The question was, with all these advantages should one go abroad? It took a tremendous time to learn a new language. He had a slight knowledge of German, but when he arrived in Germany it had all evaporated. For the first five weeks he had difficulty in making his wants known. For the first three months, although studying German six and seven hours a day, he was unable even to catch the drift of the lectures. During the next three months he was able to catch sentences from the lectures. At the end of a year he could catch the import of most that was said and felt elated over his achievement. After eighteen months he could understand all that was said, translate it mentally, and take notes in English, still unable to think in German. He said he did not believe himself duller than the average student, but that he wanted to tell the truth about medical education abroad. He believed, however, that it paid to study abroad, for the great cultural advantages and for the reason that it broadened one's views and made one capable of seeing good in the accomplishments of men in any part of the world.

Philadelphia Neurological Society.

At a stated meeting held March 26 Drs. J. H. W. Rhein and Herbert Fox presented a communication entitled "Abscess of the Brain in a Chimpanzee." The animal had been on exhibition in the Zoological Garden and had on several occasions been tested with tuberculin. While under observation the animal developed paresis of the members of one side of the body. Sensibility appeared to be uninvolved. After death three abscesses were found in the brain, one in one hemisphere and two in the other, and bacteriologic examination of the contents of these disclosed the presence of tubercle bacilli. Dr. Alfred Reginald Allen presented a communication entitled "Fat Crystals in the Spinal Cord." He reported the presence of such crystals in the posterior columns of a spinal cord that he was studying from another point of view and he discussed the question as to whether they were artefacts or the result of changes in the cord prior to death. Dr. H. H. Donaldson presented a communication entitled "Studies of the Choroid Plexus." He detailed the results of work done by several students in the University of Chicago and which tended to show that the choroid plexus possessed the properties of a secreting structure, as indicated especially by the changes in the protoplasm and in the position of the nuclei of the cells of the plexus. Dr. G. L. Streeter made a demonstration of models, showing the "Development of the Corpus Callosum."

Changes in the Position of the Heart with Increase of Pressure in the Left Pleural Cavity.—M. V. Carletti discusses the reasons for the changes in the position of the heart when the intrathoracic pressure is increased by the presence of fluid or air in the pleural cavity, and gives us these conclusions: That the heart always changes position in obedience to certain laws, and its position is intimately related to the anatomical development and modifications in position of the surrounding organs. The volume of the heart and liver, and the inclination of the diaphragm are the principal factors which influence the position of the heart. The heart changes position *in toto* toward the right, especially if it is large and the inclination of the diaphragm is slight. It changes position *in toto*, becoming vertical and rotating on its axis, so that the left ventricle becomes anterior and the right ventricle faces posteriorly when there is a more marked inclination of the diaphragm and the heart is small. It is carried to the right when the inclination of the diaphragm is great; the apex is near the xiphoid appendix, and the base is in a plane much more posterior than normal. In all three of these cases the apex is to the left of the base. There is a rare possibility that the apex may be carried to the right of the sternum further than the base when there is little inclination of the diaphragm and the heart is very small.—*Il Policlinico.*

Anomalies of the Vaginal Entrance.—Leonardo Tranchida tells us that atresia of the vagina may be either congenital or acquired. When congenital it is the result of an early anomaly of growth, before the twelfth week of intrauterine life, at which time the ducts of Müller are entirely united to form the genital tract. Such anomaly may be caused in many ways—arrest of development, circulatory changes due to trauma, twisting of the cord, infections, intoxications. Any one of these agencies may produce congestion, hemorrhage, disturbances of nutrition, which affect the trophic conditions of the organs, new growths or overgrowth of the neighboring organs causing pressure on the growing genital organs; hyperplastic overgrowth of the epithelium of the vagina causing the walls to adhere by contact. Acquired atresia may be due to general infections, or local pathological processes, in the child or adult. Such are catarrhal, croupous, diphtheritic, or phlegmonous vaginitis, obstetrical injuries, puerperal infections, and caustics used in medication.—*Il Policlinico.*

Chloroform Anesthesia Preceded by an Injection of Scopolamine.—Psaltoff concludes, from his experience, that scopolamine injections before the administration of chloroform are productive of calm sleep which suppresses apprehension of operation; that during the course of anesthesia the period of excitement is suppressed, as well as the nausea and vomiting; that the respiration is always regular, and that the patient remains quietly sleeping for several hours after the administration of the chloroform. In certain cases late nausea and vomiting have been noted, but in no instance has contracture, hemorrhage, or serious symptoms of any kind been observed. This investigator, who has anesthetized 11,000 patients with chloroform without one death, believes that the addition of the scopolamine is advantageous and should be employed. Walther reports success in this same line of work and advocates the employment of the scopolamine with the chloroform, declaring that it, together with small doses of chloroform, may be administered even to hepatic and cardiac patients.—*Le Bulletin Médical.*

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious disease reported to the Sanitary Bureau, Health Department, New York City, for the week ending April 13, 1907:

	Cases	Deaths
Tuberculosis Pulmonalis	466	200
Diphtheria	341	39
Measles	469	6
Scarlet Fever	438	14
Smallpox	1	—
Varicella	69	—
Typhoid Fever	80	8
Whooping Cough	55	7
Cerebrospinal Meningitis	17	15
Malarial Fever	..	.....
Totals	1936	289

Suppressed Gout.—Guthrie Rankin, in considering the gouty state, adopts as a working hypothesis the fact that the exciting cause is a toxemia probably originating in the upper part of the gastrointestinal tract. He regards the following characteristics as essential symptoms: gastric disturbance; a history of dietetic habits of excess, or irregularity on the part of the patient, or a record of gouty antecedents in his family; and a more or less pronounced and permanent degree of plus tension in the arteries. The writer then cites the history of two cases which illustrate different stages in the progression of this pathological condition. Neither patient had ever suffered from true gout. Both, however, had gouty antecedents, were beyond the prime of life, and had undergone more than the average amount of work and worry. Gastric disturbance was the first evidence of the trouble. Vascular tension, arterial degeneration, and threatened cardiac failure, in order led up to the brink of angina pectoris and Bright's disease. Neither patient would believe the malady to be gouty. The writer then mentions various other effects of the gouty poison aside from those relating to the vascular system. He speaks of pancreatitis as being sometimes not impossibly a direct consequence of irregular gout. The writer concludes by giving various directions concerning treatment. He considers any form of tender meat wholesome, but it should be taken sparingly. Vegetables, excepting rhubarb and tomatoes, may all be taken if thoroughly cooked. He does not see why sugar should be forbidden in cases in which there is no glycosuria. Spices, rich sauces, and pickles should be avoided. Fruit may be taken, ripe or cooked. Salt should be limited in amount in the dietary of the gouty. Constipation must be guarded against.—*The Practitioner.*

Clinical Considerations with Reference to Thirty Cases of Nephropexy.—P. Fiori says that surgical interference is positively indicated in cases of movable kidney when this is complicated by albuminuria, uronephrosis, cylindruria, hematuria, or crises of strangulation of the kidney, as well as in grave gastrointestinal complications which manifestly depend on the alterations dependent on the prolapse of the kidney; also in severe nervous disturbances with pain dependent on nephroptosis, which are not relieved by orthopedic measures. It is relatively indicated in those cases which are benefited by orthopedic treatment in which there are not anatomical changes in other organs resulting from the position of the kidney. It is contraindicated in splanchnoptosis unless the condition is aggravated by intrinsic kidney changes of a nephritic type. When associated with genital lesions treatment for these is to be used, except when there is a blood dyscrasia resulting from the general condition. Nephropexy is allowable whenever all other means of treatment have been tried without relief and the symptoms, especially nervous, are increasing. Fortunately the perfection of the clinical indications makes this a rare proceeding of last resort, and its value is enhanced on account of the absolute harmlessness of the operation.—*La Riforma Medica.*

The Removal of Foreign Bodies from the Esophagus.—Franke has found that it is not always necessary to open the esophagus in order to remove foreign bodies which cannot be extracted by instrumentation through the mouth. The method he recommends if the foreign body is in the upper part of the esophagus is to cut down upon this tube in the manner prescribed for esophagotomy, but before incising the esophagus to locate the impacted object. In many cases it will be found possible, by careful manipulation from without with the fingers, to work it gradually upward until it can be reached with an instrument passed through the mouth. Franke describes one case in which he was able to extract in this way a set of false teeth which had been swallowed and had become impacted in the upper part of the esophagus, and he advises that this simple maneuver should always be resorted to before exposing the patient to the risks that accompany esophagotomy.—*Zentralblatt für Chirurgie.*

Milk and Tuberculosis.—Marchand refers to the work of various modern investigators in this subject. A number of authorities, including Calmette and Guérin of the Pasteur Institute, have concluded that the principal portal of entry of tuberculosis into the organism is the intestine, and that this disease can be introduced by the ingestion of milk taken from tuberculous animals. Every infectious malady of the cow renders its milk dangerous to the health of the consumer. Even the food eaten by the cow influences the quality of its milk. But cooking the milk—sterilization, pasteurization, or boiling—distinctly modifies its constitution. Such a process tends to convert the lactose into caramel. A part of the albuminoid element it makes insoluble. It affects as well various salts contained in the milk, especially those necessary to the bony tissues of the new-born. Even if it kills the injurious microbes, it has, nevertheless, the disadvantage of destroying the natural digestive ferments which the milk contains, besides changing its taste. Recent investigations show that next to maternal milk normal raw milk from a healthy animal, and naturally sterile, offers the best conditions of alimentation for young children. It is also the best form for patients or old people. The writer calls attention to the importance of employing tuberculin in order to distinguish diseased animals from healthy ones. The greatest care should be taken to use the milk of healthy cows only.—*Le Nord Médical.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended April 12, 1907:

OBSERVATIONS ON ARTERIOSCLEROSIS.

By H. NEWTON HEINEMAN, M.D.,

BAD NAUHEIM, GERMANY.

Arteriosclerosis before old age is a disease of exhaustion and of excess. The term angiosclerosis is used because veins as well as arteries are often affected. Atherosclerosis is suggested because atheroma is a stage of arteriosclerosis.

The disease is increasing steadily in America, and even Germany shows 22 per cent. in 11,000 cases of general mortality.*

Etiology.—Pressure in ordinary physical or mental daily labor with want or excess in life's accessories maintained for long periods, especially in neurotic subjects, acts to cause arteriosclerosis. Excess in stimulation, whether in tea, coffee, tobacco, alcohol or prolonged improper diet, which alter the alkaline blood reaction and constituents are contributing causes.

Age.—Appearing rarely in the young (shortly after puberty), it is usually specific before 40 years, occurs generally between 45 and 55 years, later generally approaching the usual senile type. Sex shows in favor of the males, as comparatively few women are affected. Inheritance† acts here as elsewhere through inherent weakness. Mental worry, strain, and neurasthenic conditions generally are of the greatest moment.

Gout and rheumatism are noted in one-half to one-third of all cases, and their acute form in older persons may start the trouble.

General infections, most commonly typhoid, influenza, scarlatina, diphtheria, severe follicular tonsillitis, erysipelas, in about the order stated, but also all exanthemata and infections, including malaria, are its causes, and especially when aided by predisposition and later exciting agencies. Local suppurations may in rare cases inaugurate slow vascular change.

Syphilis in from 15 per cent. (my own) to 35 per cent., according to individual practice, accounts for it.

Toxins.—External and internal toxins, whether from fatigue or from the body as in certain forms of obesity, diabetes, etc., from prolonged intestinal autointoxication, from vicious habits of overstimulation, or from atmospheric surroundings, such as noxious vapors or any poisoned atmosphere cause it

External injuries, such as repeated injuries to vessels by work, or excessive use of certain extremities, affect its origin and locality.

Pathology.—Normal circulation requires an unirritating medium, normal heart, and vessels, normal cardiac and circulatory vasomotor centers and nerves, and normal lymphatic conditions.

Arrested circulation at some point with intravascular irritation are cognate active requirements for arteriosclerosis. When, therefore, from circulating toxins and irritation within the vessels, local congestion, spasm, or other slowing of blood exists, then physical or mental overstrain causes in even greater degree than it does normally an aggravated state of circulatory arrest or spasm, and both required conditions are rendered more active.

Experimental pathology in the hands of Josué, Erb, Jr., and others has produced aortic and arterial changes in animals with the use of adrenalin injections. These changes resemble those of the senile and work type of arteriosclerosis with its marked calcareous degeneration, but with less or almost no intima lesion. These results bear largely upon our subject, but the exact function of the circulating poison introduced, and the element of spasm created, are still subjects for clearer definition.

The vessels in arteriosclerosis are generally diffusely affected, less often with nodular thickenings. All sizes of arteries may suffer. When veins are involved they have generally been previously acutely inflamed. Any set, single artery, or branch may be extensively or slightly engaged, leaving healthy places between. Internal arteries may be changed, while those of the extremities are little or not so, and the reverse. Influenced by the considered causes, certain arteries are more frequently involved; anatomical statistics vary, but approximately the following is the order of sequence: renals, aorta, splenic artery, crurals, coronaries, cerebrals, etc.

The primary and secondary lesions worthy of special reference here are these, among others:

Cardiac: muscle degeneration (myocarditis) with infrequent cardiac nerve involvement.

Renal: sclerosis of vesels and other changes producing the characteristic small asymmetrical irregularly granular kidney, with decided cortical changes specially marked in the glomeruli. Other varieties or hybrids of the granular, the chronic diffuse, and the parenchymatous nephritis may be found. Atrophic suprarenal capsules exist at times.

Splenic, and less marked gastric, mesenteric, or intestinal arterial changes result in visceral changes such as fibrous pyloric thickening, gastric and duodenal ulcer, intestinal thickening, atrophic spleen, or pancreas and chronic peritonitis. Such a gastric ulcer is here presented by specimen, such a duodenal ulcer was demonstrated to me by Dr. Longcope (Philadelphia).

Microscopical changes early show fat cells crowding the interspaces and fatty degeneration in the cells of the intima. This stage or condition, common also to anemia, etc., and therefore not characteristic, may clear up. Next the fat globules drop out of the changed cell bodies, cell proliferation occurs, new connective and cicatricial tissue takes the place of the intima, its few elastic fibers also suffering. Such changes often escape any but the closest scrutiny. Coincidently or subsequently other more patent

*Bahrdt: Leipzig Life Insurance Companies. Cong. f. Inn. Med., 1904.

†Huchard and Frank speak of hereditary aortitis.

pathological changes in the intima and media take place, those in the latter or former ultimately predominating according to type. Finally, the process passes from one to the other, or all of the three coats, least to the adventitia,* involving them in varying degree. Further cell production with new elastic formation, fatty degeneration, and atheroma of varying amount, with or without calcification, constitute successive changes. Atheroma† is simply degenerative change in the sclerotic tissue, and cannot anatomically or clinically be differentiated. The atheromatous degeneration often leads to erosion and secondary thrombosis (well seen in aneurysms, etc.)

Certain distinct types appear to present themselves pathologically.

The "specific type" involves the aorta generally, and the arteries of the nervous system (cerebral and spinal) more particularly. It advances along the aorta by sharply defined segments. It is mostly a media disease (mesarteritis) in the aorta, and produces cicatrices which decidedly involve the adventitia, also the intima, and give rise to a distinct multisacculated appearance of the aorta. The media may contain gummata or other specifically characteristic tissue, but the *Spirochæta pallida* has been found in only a few cases. It generally leads to aneurysmal formation.

As a post-syphilitic disease arteriosclerosis occurs not infrequently in the ordinary diffuse variety without any specific characteristic lesion. A special general arterial nodular form with specific microscopic tissue lesions, generally, however, as an acute affection known as periarteritis nodosa, occurs, and has been studied by Kussmaul, Bostroem, Mönckeberg, *et al.* Its specific character was formerly overlooked.

The "senile and labor type" involves the lower extremities most commonly, often the upper or both, and has marked calcareous change. Infrequently it is seen as a noncalcified type, with diffusely thickened tortuous vessels of almost the entire body. The heart is often relatively normal at times, may have moderate coronary thickening or advanced (non-disturbing physiological) coronary change, aside from muscular changes.

The "renal type" is the best understood with its granular kidney, general arteriosclerosis, hypertrophied left ventricle, and frequent termination with cerebral hemorrhage or aggravated renal trouble.

The "myocarditic type" with multiple arteriosclerosis, small or great, in various parts, marked myocarditis, is often complicated by embolism, and terminates from cardiac failure.

Clinical History.—Some cases of arteriosclerosis occur in young, growing persons, and are usually associated with a congenital or acquired (at puberty) insufficient vascular system. In a few of the working classes the working type of arteriosclerosis appears early in nervously disposed persons; possibly syphilis may influence this in some of them.

In adults under forty years of age syphilis is always to be thought of, and early apoplectic strokes arouse the same suspicion.

To us it has appeared that, apart from the renal form, most cases appear to present features in which one of three groups of symptoms predominate besides the generally prevailing ones. These are either angina, anginose, or angiospasm symptoms or signs, again myocardial, and thirdly neurasthenic.

The renal form, hitherto erroneously accepted as the type of all, manifests itself, as is well known, by long-continued occipital pressure and headache, a sense of fullness of neck, eye symptoms (recognizable in 30 per cent. of the cases), but which eye symptoms often improve later, advanced urinary signs as persistent granular or epithelial casts, and albumin in larger amounts, later by apoplectic strokes or uremic symptoms.

In all forms of arteriosclerosis, and more especially in those well established, disturbances of digestion are not only precursors of progressing disease, but become pronounced with its advance. Gastric and intestinal digestion becomes slow and imperfect, meals are longer in digesting, and the former quantities are not digested. Symptoms of gastric dilatation are not unusual, indigestion, gastric, and intestinal catarrh, oxaluric symptoms, and hepatic disturbances are very common, and abdominal arteriosclerotic colic appears.

Autointoxication from fermentation, constipation, or more directly from any diminished blood protective power or active bacterial increase is at all times a threatening factor of the disease. Constipation becomes very harmful, and, if persistent, often excites angina from autointoxication or from irritation, and nothing is more dangerous at such times than indiscreet diet, particularly game and fermentable food. Such errors as dilution and weakening of gastric juice by mixing quantities of liquid food with solids, induce serious cardiac difficulty mechanically from gastrointestinal overdistention, besides increasing the danger of autointoxication.

The presence of myocardial signs and symptoms is common to all groups. Heart signs which are most commonly met with are intermissions, arythmia, and changed character of heart sounds, with or without murmurs.

Aside from hemic and other subsidiary murmurs, simulated or secondary murmurs from a disturbed valvular orifice mechanically affected by the lesion in an adjacent orifice, are also to be reckoned with. Mitral stenosis is thus infrequently simulated in old arteriosclerotics from rigidity about the aortic valves, just as aortic regurgitation is sometimes simulated in severe mitral stenosis in the young.

The heart sounds are characterized by the lesions of myocarditis or of high blood-pressure, variably one or both. Absence of more or less muscular quality, and partial or complete hollow quality of first sound, are common with accentuated second sound. The more hollow the first the shorter and less clear becomes the whole second sound, always a matter of serious import. Intermissions longer or shorter are frequent, and depend, as they really do in most of their occurrences, upon reflected gastric, intestinal, or hepatic disturbances, if not upon direct autointoxication. Cardiac intermissions, while never desired, may be no indication of immediate, often not even remote, gravity, and in cases sometimes a sign of comparatively good import. Thus the occurrence of intermissions in late stages of threateningly fatal pneumonia gives a ray of hope even, for now the pneumogastric is controlling conditions somewhat.

Arythmia is frequent, often present for years in certain cases, and, if the irregularity be regular, less important than usual.

Tachycardia and bradycardia are both important and frequent, the latter less common, and both induce more serious trouble. The former is often met in neurasthenic or nervously disposed persons.

* Incipient adventitia changes arise from local causes, like injuries, etc.

† Two specimens were presented, one specific (36 years) and the other a senile aorta (80 years), with marked arteriosclerosis, without calcification or erosion showing diffuse atheromatous change, as proved by the red spots in intima and media produced by proper aniline stain.

Both must be considered relatively to the patient's normal pulse rate, and may be consistent, barring short lapses, with apparent good health for years if kept in check.

Angina may exist in its various types, and may occur in the mildest forms, often called false angina; it may present only parts of its characteristic phenomena of localized pains by sensations variously limited about the chest, neck, or arm; or the signs of facial and pulmonary angiospasm causing flushes with heat and dyspnea, and hurried breathing, or congestion of serous membranes, more commonly the pleura, of internal organs, the pulmonary, renal, hepatic, or of pharyngeal constriction, laryngeal obstruction; least serious is when swellings of the hand or arm, of the supraclavicular fossæ, or anywhere in the integument, occur, which latter are rarely accompanied by the heat and redness of erythemata. Angiospasm of the radials during angina attacks the artery, these varying in diameter, being in the same case alternately small and large, in others dilated during the attack, but in all cases evidencing high tension.

In the average case the disease may announce itself from a clear sky with angina pectoris and precordial or poststernal oppression, together or separate, and with various heart irregularities.

Dyspnea is apt to be a marked early symptom, less so later until complications such as aggravated hepatic, gastric, renal, or cardiac conditions set in.

Cardiac asthma with, in early cases, slight or abortive angina, becoming more pronounced later, is a frequent decided chest symptom.

Cheyne-Stokes respiration appears during times of intentness upon mental or physical work, when patients can be unobtrusively observed, and often in sleep, during apparent health. It is of course well known in serious conditions, as is also the Adams-Stokes phenomenon most commonly met in severe bradycardia.

Renal symptoms, such as occasional albumin and hyalin, with less frequent slightly granular casts, are found in two-thirds of our personal cases. Often nervous, or again digestive and hepatic disturbances from dietary errors, cause their reappearance.

The next important group is that which begins with nervous or neurasthenic symptoms: vertigo, irritability, and increasing difficulty in continued work and fear of it, unsteady handwriting, slight hesitancy in speech, especially when excited, impaired memory and mind, depression, emotionalism, and lacrymoseness, most important of all insomnia, and not infrequently melancholia and suicidal tendencies of a mild type, which disappear later.

A certain number of patients, more especially women, show early symptoms of bad air effects when in overheated or badly ventilated rooms, particularly in public, when oppression, dyspnea, faintness, tachycardia, cardiac irregularity, with generally nervous flushings and fear supervene. The intimate relation of neurasthenia and arteriosclerosis is especially worth noting.

Vasomotor Disturbances.—The importance which abdominal arteriosclerosis assumes, the changes which closer investigation will demonstrate in the abdominal plexuses, just as has been demonstrated in a moderate number of cases in the cardiac plexus, has special significance in producing the class of disturbances already described, and which may be accentuated under this heading. Angina from an apparently cloudless sky, or from varying neurasthenic influences, with its condition of small and contracted arteries during the attack, succeeded in some cases at its maximum by apparently paralyzed or widened peripheral arteries having equal or almost equal high pressure in both the contracted as well as the dilated condition, and passing over to the danger point, when the pulse becomes markedly quickened, is a condition which is significant. Congestions of portions of the face and mental disturbance replacing angina, and occasionally masking it and calling forth hysterical manifestations or associated nervous phenomena and the numerous angiospasms, are not uninteresting appearances.

Blood States.—Anemia in its various form is common. Often pernicious anemia is simulated in women, but the absence of macrocytes and nucleated red corpuscles differentiates this.

Blood pressure presents high tension during a certain stage of all cases, declining to a later low tension, or varies under nervous, cardiac, renal, digestive, blood, and special localized arterial conditions, such as diminished aortic elasticity.

Only 18 per cent. of my own unequivocal cases showed normal or lower pressure. Dunin, in examining 420 cases, found 300 (71 per cent.) with pressure above 150 mm. and 120 (29 per cent.) with low or normal pressure. Casting aside one-third of the 120, 80 (21 per cent.) unequivocal cases of the latter remained.

Von Basch has divided arteriosclerosis upon a combined symptomatic and pressure basis into: true arteriosclerosis when pressure is over 150 mm. with more or less persistent albuminuria, latent sclerosis with over 120 mm. and under 150 mm., and pseudosclerosis with 120 mm. or under, each with certain symptoms and signs. This division, except with the experienced, may lead to error.

The absence of symptoms referable to the heart condition met with not infrequently in the senile and work type, when coronary change is suspected and found at autopsy, is worthy of notice, and finds this physiological explanation: that so long as some initial impulse-giving muscular fibers about the venous sinuses remain, and a sufficiently contractile continuous muscular conductivity in the ventricle exists, fair heart action is possible. In other words, the sclerosis here does not menace the most vital heart portions, or else insufficiently, or, again, the gradual coronary change may have undermined the muscle less. Again, quiet disposition may influence this absence.

It is interesting to note the tendency in the mental and city patient towards central lesions, while in the purely senile, the labor, and country patient that towards peripheral lesions predominates.

Limping gait, described by Charcot and Erb, is characteristic of some cases. Carious teeth, as an accident or incident, are often met with.

Diagnosis and Differential Diagnosis.—The diagnosis is based upon the clinical history pointing to old infection of some kind, unusual persistent mental or physical strain, either or both, abuse of stimulant of any kind, symptoms of gradually increasing irritability, insomnia, difficulty in ordinary mental processes, with some cardiac and either gastrointestinal or renal symptoms, or all accompanied by signs of decided cardiac weakness or irregularity, or both, with altered heart sounds, recognizable change in pulse trace, and pressure and ophthalmoscopic changes. Naturally, as the arteries of different portions of the body are more or less greatly involved, whether the cardiac, the gastric, the cerebral, or others, the symptoms and signs will be more intense in their direction, as when with aortic and cerebral vessel change we may have neck and head rhythmic pulsation, so do other marked symptoms and signs occur in other combinations.

In the pulse tracing care must be taken to separate the early and the postmyocardial trace. Then, too, the venous pulse trace has value for judging the right heart, as the radial has more particularly for the left. I advise the use of the simple Dudgeon (unimproved) to begin with, and later the use of the Mackenzie or Jacquet* for two or three combined traces of pulse, apex beat, or venous† impulse, under the following precautions: (1) Adjust straps properly, using a right and left arm arrangement; avoid the tightening under the wrist, making it at the outside. (2) Take the lowest of the most characteristic traces obtainable, not the lowest trace of any kind. (3) See that trace is in the middle of the tracing paper. Above the middle may mean over, and below the middle, underpressure of the instrument. If a proper midway trace is impossible for any reason, note it always. Such tracings are always open to question. They become valuable under similarly noted conditions of other observers. (4) Always take every kind of trace singly, as well, so as to judge the correctness of each individual trace in a combined series.

In pressure the following observations are important: (1) The time of day affects the pressure, for it is apt to be higher after meals and in the morning in certain cases. A restless night lowers pressure. Pressure varies with mental state, medication, etc., and should be repeatedly taken. It should indicate arterial (P.A.) or capillary pressure (P.C.) in records. Then, too, systolic and diastolic pressure have value, and so has the differential pressure of these latter. (2) The instrument should be properly tested, well understood by the observer, so that he knows his own personal equation of error and its relative value to other instruments. My own preferred instruments are an Oliver of the old type besides the Boulimié‡ or combined Potain-Gaertner instrument, and occasionally the Riva-Rocci improved (Janeway).

Radiogram.—In seeking to decide questions of uncertain cardiac enlargement or of sclerotic arteries, I have this to say: The expert upon this subject, Geheimrat Prof. Moritz of Giessen reported (three years ago) that it gave him the correct right border in 68 per cent., the correct left border in 70 per cent., both borders correctly in 50 per cent., and both borders wrongly in 12 per cent. Despite the fact that no adequate picture is as yet obtained except in calcification, which in external arteries is appreciable to the finger, it is of great value in such aortic conditions, of confirmatory value in heart cases, and of diagnostic value in emphysema, chest deformities, etc., when other methods are dubious.

We must remember that Roentgen pictures are silhouettes. The source of light, its direction and intensity, if allowed to vary, give different results, as does also the least variation in the patient's position. A flat, wooden, unyielding table, marked off in squares on the top and bottom, and a quarter-inch metallic (lead) strip at the nipple level attached to the table across underneath, the patient laid on the table with shoulders, certain ribs, and other anatomical points plumbed to their respective squares on the table (and recorded), and the metallic line projected through the nipples in the photograph, give the only satisfactory results. Sitting or semiprone postures give doubtful pictures.

Well-marked angina pectoris, always the strongest evidence of coronary arteriosclerosis, points to probable general arteriosclerosis. Persistent or oft repeated angina within the twenty-four hours, despite careful (sedentary) and regulated habit and nitroglycerin administration, always points to coronary sclerosis with marked cardiac dilatation, even when percussion and auscultation leave a doubt. Exceptionally in phlegmatic and well-ordered persons, even marked coronary sclerosis may present only signs of myocarditis when aortitis is absent.

In marked aortitis, of which coronary sclerosis usually forms a part, some aortic dilatation is present, the aorta (and the right subclavian artery) is sometimes within reach, there is neck and head rhythmic pulsation (Musset sign), and the greater transverse aortic dullness can often be made apparent early by first gently percussing, noting its transverse area, then striking five or six finger blows over the aorta, when repercussion will show a diminished area (Cherchewsky). Retrosternal pains are more or less constant, the radials are unequal, often show the aneurysmal trace, and a roughened coronary artery projecting into the aorta may cause a loud obstructive murmur.

Myocardial cases manifest the symptoms and signs referred to, of the changed heart sounds, the first being early, parchment like, the second comparatively or really reinforced. When the first is distinctly hollow or tubular and the second thin, like the snapping of thin cord, marked dilatation exists.

A gouty history and gouty symptoms, and strong uric acid and its related conditions, accentuate the suspicion of arteriosclerosis.

Prognosis.—A recent authority has said: "From a general standpoint nothing can be done (except in syphilis) to lessen the existing influences upon the diminished arterial resistance." To this opinion I take decided exception. In 1895 I heard the pathologist, Thoma, say, "by avoiding the causes of increasing blood pressure, by proper hygiene and regimen, serious and fatal vascular disease might be anticipated. If it became possible to recognize arteriosclerosis sufficiently early, it would be easy to limit the danger of rupture of blood-vessels and aneurysmal formation."

My labors for the past ten years along the latter indicated lines have taught me their truth, and that well-directed medical experience and a patient's intelligent aid can check the increasing danger. Readjustment of physique and work, not always retirement from work, are needed on the patient's part. Are not five, eight, and ten years' prolongation of life, with more or less working capacity and in comparative comfort, as Nauheim has frequently demonstrated, of value? Is not one year, even, with clearer mind, restored mental balance, and ability to enjoy life, as I have seen, worth a struggle? In ten years at Nauheim, with many hundreds of such cases, mostly serious, the mortality during treatment has been three-fourths of one per cent., and in all my cases the entire mortality, including those who died at home any time after treatment to date, 2.6 per cent. (under 3 per cent). And I add here that no patient has died at sea. The dangers are, when landing, from overdoing and from the new temptation to indulge in food and drink to excess.

Treatment.—The treatment implies mental and physical adjustment of the patient to his recognized condition, besides the physical and internal remedies to undo or prevent further trouble. Work must be diminished and limited for a long time to what is essential, and sources of irritation removed or ignored. A proper methodical life, hygienic surroundings, proper diet, regulated sleep and rest periods,

*The Jacquet instrument with two tracings is more practical than that with three.

†Use grooved venous pulsometer.

‡French standard 10 or 12 equals the German and others of 100, 120, etc.

and above all properly controlled method in everything, constitute the only safeguard against increasing disease, life with pain, or unnecessary earlier death. Well-aired and not too warm apartments never over 68° F., and for sleeping apartments as much less as the patient can bear, should be our aim, but brought about by careful graduation in the overheated American homes. Sleep in most cases of not over seven hours continuously, with rests during the day or a regular afternoon siesta, is best for most of these patients, a rule well applicable to most of our cardiac cases as well.

Daily exercise, as riding, driving, mild limited gymnastics in the room, all carefully directed, adjusted, and varied (guarding against overuse of the left arm and hand to prevent needless heartstrain), walking on the level, and later up moderate ascents. Respiratory exercises are indicated, as are also resistance movements (manual for a time), then in appropriate cases by the Herz or Zander system. When exercise is limited from whatever cause, massage* is most necessary, which may be followed by frictions. Dry frictions in the morning, with cool or cold sponging before retiring (the latter induces sleep), or reverse operations as to time. In some cases the morning cool or cold sponging or plunge is well replaced by warm dips.

Bath Treatment.—While fresh water baths often disagree, saline† warm baths are generally well borne. When saline baths cause discomfort, partial body immersion, enough to cover legs or more and douching the upper body, coincidently overcomes it. The happy influence of the saline carbonated baths, natural when possible, and otherwise artificial, is of far-reaching value in this affection. The special virtues of Nauheim, in relation to arteriosclerotic treatment are herewith affirmed after seventeen years of impartial observation and practice. In his recent work, Romberg of Tübingen corroborates another recent utterance of a great German scientist as follows: "Among the natural carbonated baths, Bad Nauheim, by reason of its wonderfully graduated baths, its excellent arrangements, favorable situation, and special local influences, unquestionably ranks first, and is to be recommended in all cardiac insufficiencies."

Diet.—Dietary directions constitute the most important of internal remedies, and its immediate permanent control in urgent cases, its gradual regulation in all in the course of a few months or less, absolute limitation in all after six months or a year, and final permanent restriction in every instance, are imperative. Avoid sudden revolutions, but always limit quantity and quality. Discard hearty meals, and in some cases give light food between.

Avoid fluids with ordinary hearty meals, giving up soups, especially meat soups, and confining the use of all fluids to 4 or 6 ounces at the meal. In proper cases permit fluids between meals. When digested, milk is best of all. Coffee should be discarded (save a few drops in milk when seemingly needed), and replaced by milk or freshly infused weak tea. In habitual tea drinkers, tilleul (linden tree flower infusion) may be substituted.

Increase vegetables and diminish meats. Use white meats, save in those with anemic tendencies, when red meat may occasionally be needed. Substitute digestible fish for even some white meat. Exclude game, save fresh white game.

Discard sweets and starchy desserts, overseasoning, spices, and condiments.

Test by accepted methods the digestibility, and the equally important assimilabilty of indicated articles of diet in individual cases, so as to select the best.

Reduce alcohol and tobacco, finally absolutely; gradually but without much delay all alcohol should be limited to small quantities of whiskey (a few tablespoonfuls) with water for gouty subjects, for others a glass of good claret or a not heavy but sound Moselle, all diluted equally with water.

Occasionally for a fortnight or longer in marked renal cases give milk diet partial or complete, especially when well borne. In all cases avoid fresh bread, which should be well baked and stale, and often may well be replaced by light soda biscuit, zwieback, and the specially made toasted rusks.

Digestion aids, antifermentatives, and relief for constipation rank first in the internal remedial agents. Six to eight ounces of vichy three-quarters of an hour before meals, gastric massage before meals, the various digestive aids, muriatic acid (German) among the rest; beta-naphthalin, creosote, salol, etc., and laxative agents find place. The important indication of antiautointoxication treatment is best met by food control and regular evacuations, helped by medicines where required. In these directions calomel for hepatic, intestinal, and antifermentative relief is a sheet anchor in this disease. Repeated doses at bedtime for a series of days or else weekly administration, or both for various lengths of time, are imperative. A combination of calomel gr. 1-4 to gr. 1, euonymin and sodium bicarbonate, each gr. 1, well triturated, given at night, and followed by a mild saline in the morning, is a favorite remedy with me. The arteriosclerotic intestinal colic is often relieved by horizontal rest.

Constitutional Treatment.—Iodide of potassium in 3 to 5 grain doses, continued for months or for one or two years with interruptions, or iodide of sodium, which is less potent and rather more of an antispasmodic, at first giving a few grains at night only, are universal favorites.

Trunecek serum and simlar remedies, which are composed of potassium, sodium, and allied salt mixtures, may replace the iodides at times, and also act as alteratives and help to diminish pressure. Ovarin and lutein, both organic derivatives, certainly diminish pressure and are efficacious in women. Lactoserum derived from milk has also been used of late years. The exact effect of these agents as direct antispasmodics, and their effect upon blood ferments and corpuscles, is variously attributed to blood realkalinization in diminished alkaline states, to white corpuscle increase, and to catalytic body introduction.

Arterial pressure reduction is more immediately attained by the specific agents, the nitrites, such as nitrite of amyl, nitroglycerin, etc. Nitroglycerin in as small doses (1-200 to 1-100 grain) as will keep the patient comfortable, not fearing the largest doses (gr. 1-50 to 1-20), may be maintained for months when needed, and reduced to a minimum, or entirely, when indications cease, when congestion, angiospasm, or angina ceases, or when pressure becomes and remains not excessive. Anticipatory doses often save large ones.

Myocardial indications are met in the usual way by cardiac agents, as irritable, spasmodic, or relaxed action indicates. Recognizing how digitalis leaves and preparations may vary, standard solutions of recognized firms only should be used. A standard fluid extract (one or two drops), the

*Massage must be moderate. Vigorous abdominal massage may increase blood pressure and cause intermission, that of the back and legs often reduces the pulse.

†Three to five pounds of common sea salt makes an artificial saline bath, to which carbonating salts or carbonated water may be added.

French Nativelle solution of one milligram of digitalin, or the German digitoxin derivatives may be given in small doses for long periods, or in full doses for immediate effect (remembering that in ordinary doses the full effect of digitalis takes forty-eight hours). Strophanthus (European preparations are two to four times stronger), spartein, or convallaria can be given for a long time.

Anemia.—This important indication may be met in the usual way, or else by arsenic substitutes hypodermically, such as cacodylate or methylarseniate of soda (0.03 on alternate days, later daily, or up to 0.05 for two or three weeks). Oxygen in daily inhalations, beginning with 15 to 20 liters, later 30 to 50 liters, avoiding overstimulation, is useful.

As general aids, we have electric treatment by current (D'Arsonvalization, etc.), or by light (Finsen) in individual cases. In gouty subjects the uric acid and allied tendencies are improved by stated use of urinary antiseptics. Insomnia, so common, is relieved by always avoiding brain tension in the evening and excitement by day, by light, early evening meals, sometimes adding a biscuit, etc., when needed before retiring, by late sponging, and by bromides, valerian tincture, etc.

Physiological salt solution by hypodermic or rectal injections often replaces diminished water supply.

The work of Zirkel and his disciples in osmology, and the labors of Wright in opsonology, are worthy of our highest attention in their influence upon our therapeutic endeavor.

MALIGNANT DISEASE AND MALARIA.

WITH REFERENCE TO THEIR SUPPOSED ANTAGONISM.

By Major CHARLES F. KIEFFER,

SURGEON U. S. ARMY, FORT D. A. RUSSELL, WYOMING, ON DETACHED SERVICE WITH THE ARMY OF CUBAN PACIFICATION AT SANTIAGO DE CUBA, CUBA.

Frequent comments have appeared on the apparent relative immunity of certain tropical peoples to malignant disease. The belief was quite widely held, and indeed is still held by some, that this is especially true of the tropical countries most severely infected with paludism. The idea is very old that a patient afflicted with cancer may lose his tumor after a sharp attack of malaria, and many striking cases are on record which lend color to the idea that there may be some antagonism between the two diseases.

About five years ago F. Loffler advanced the idea that the apparent immunity to malignant disease in tropical countries was due to the fact that in these countries practically the entire population had at some time or another in their lives suffered with severe paludic infections, and that the antagonism between the two diseases was the underlying cause for the absence of cancer. Following out this idea, he made the suggestion that cancer might be combated by inoculation with malarial parasites.

Following this suggestion, numerous papers have appeared tending to show the fallacy of the premise on which this theory is based. Reports were made from countries intensely malarial in which the death rate from malignant disease reached quite a respectable figure. Thus, Kruse (*Archiv für Hygiene*, Bd. XII, Hft. 3, 1902) studied the cancer and malarial statistics of Italy, and found that, despite the very general distribution of malaria, cancer is quite as common there as it is in Prussia, where malaria is almost nonexistent. Also Prochnik (*Wiener klinische Wochenschrift*), reporting from the South Sea Islands (Dutch India), finds that malaria is of no effect in the control of carcinoma. Malaria is so common in these islands that there are few, if any, of the inhabitants, foreign or native, who escape the infection. Carcinoma is stated to be also fairly prevalent, and, generally speaking, is more common among the natives than the foreigners. Indeed, the author has observed numerous persons suffering from both conditions at the same time, and he has never seen the slightest amelioration of the carcinomatous condition. He believes, in fact, that malarial infection, far from being preventative of carcinoma, is the indirect cause of the large proportion of malignant disease of the liver observed in those islands.

On the other hand, to show that where the disease is relatively absent in tropical countries, the diminution is not due to malaria, but to some other cause or causes, J. Goldschmidt (*Deutsche medizinische Wochenschrift*, July 10, 1902) cites statistics from

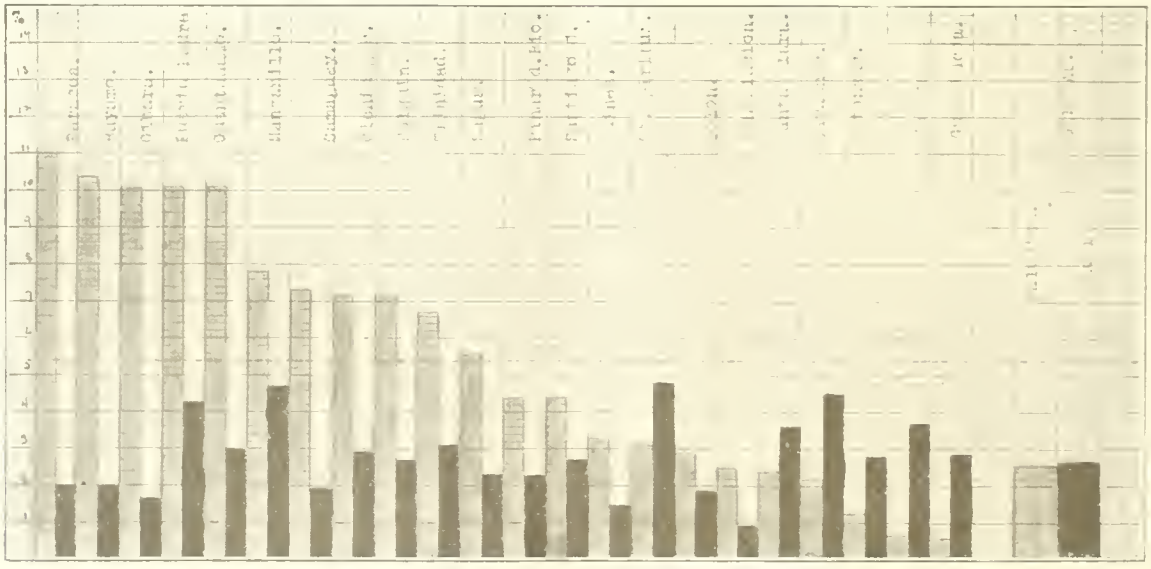

CHART 1.—Showing [illegible] cancer and malaria [illegible] more than [illegible] inhabitants in Cuba for the years 1894 and 1895; the light line denotes malaria; the black line, cancer.

the island of Madeira. In this island malaria is practically unknown, and at the same time the figures show that carcinoma is also a rare disease. He thinks it is very reasonable to suppose that if malaria and carcinoma are so distinctly antagonistic, then in the absence of the former the island should show a larger proportion of cases of the latter

disease. Robertson (*Journal of Tropical Medicine*, November 1, 1905) cites cases to show that malignant disease is fairly prevalent in the Gilbert Islands.

A considerable and varied experience in tropical practice has convinced me that malignant disease is relatively less frequent in hot countries than in cold countries, but, while in some hot countries it is extremely rare, in others it is quite a factor in the morbidity and mortality. When the distribution of

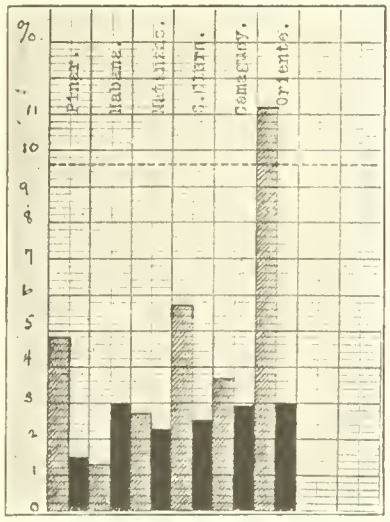

CHART 2.—Showing the percentage of total mortality due to malaria and cancer in the six provinces of Cuba during the year 1904. The light column indicates malaria; the black column cancer.

malignant disease in the various countries, or better still in the various towns and provinces of a country, is studied, it will be found quite independent of the distribution of paludism in the same regions. As far as individual instances are concerned, I have frequently observed carcinomatous patients suffering from intense malaria. In two cases severe explosions of latent malaria were observed after operations for the removal of malignant growths, and with no effect on the later recidive and fatal termination. Davidson reports the death of a European from cancer of the stomach who was stated to have suffered from frequent attacks of malarial fevers. Prochnik (loc. cit.) observed the concurrence of the diseases in "numerous cases." Cardamitis (*Grèce Médicale*, Vol VI., No. 3) encountered cancer associated with malaria, and consequently denies that there can be any antagonism. He has, in fact, witnessed the development of malaria in a woman with an operable cancer after she had been bitten by infected mosquitos. There was no demonstrable variation of either disease process.

There is an undoubted relative racial immunity which is not necessarily confined to tropical peoples. Kruse, in the paper already cited, calls attention to this fact. Cancer is more common in northern than in southern Italy, and the ethnological differences between the inhabitants of the two different sections is marked. He believes that the Alpine country gives evidence of a race distinctly more prone to malignant disease, and that this race helped to stock southern Germany and northern Italy. For this reason the prevalence of cancer in Continental Europe increases in the direction of the Alps. In the tropics this relative immunity is helped out by the simpler mode of life which the natives pursue, and particularly by the absence of many of the forms of continued irritation which we know lead to malignant disease. I am convinced of the correctness of the observation that improvement in native races in the way and mode of life of civilization is followed by increase in the rate of malignant disease. In many tropical countries increasing civilization means a more or less complete adoption of European modes of life, and of these principally excessive meat eating and increased consumption of alcohol. Both of these are, I believe, powerful indirect factors in the production of malignant disease. In many instances, when the tropical native eats little meat, it is not on account of any aversion to it as a food stuff, but because it is usually beyond his means. Where he has the means, then he becomes, as a rule, as excessive a meat eater as either the average European or the average American.

In the Philippine Islands malignant disease is not rare. In a restricted surgical practice among the natives, I saw numerous cases of skin cancer and extirpated four cancerous breasts. I was particularly impressed with the number of cases of malignant disease of the penis encountered. I then thought it a coincidence that I saw in a short time six cases of well-developed epithelioma of the penis. Since coming to Cuba I have seen several more, and it will be observed in the figures from the General Hospital at Santiago that among the operations for malignant disease there is an unusually large proportion of cases of malignant disease of the penis Able Cuban practitioners seemed surprised when told that epithelioma of the penis is among the rarer manifestations of malignant disease in the United States. I have not been able to discover any etiological factor. I have no figures bearing on the frequency of malignant disease in the Philippine Islands. My experience was, however, that I saw about the usual proportion of these cases to other pathological surgery. There certainly was no such marked disproportion either way as to call attention to it. Since coming to Cuba I have studied the

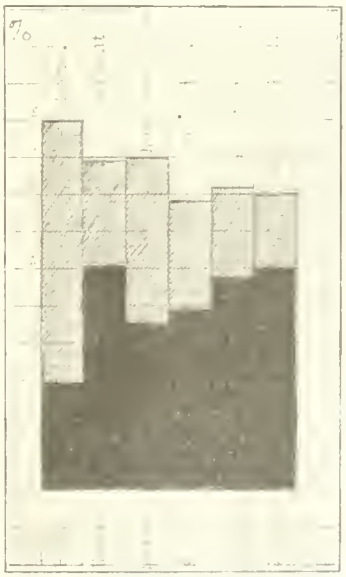

CHART 3.—Showing the percentage of total mortality due to cancer in the six provinces of Cuba during the year 1904, compared with that in the six New England States in the year 1900.

question carefully and compiled all available data, and the following interesting charts and figures are the result.

Chart No. 1 shows the percentage of the total mortality from paludism and cancer in twenty-two cities in Cuba exceeding 20,000 population. These figures are compiled from the monthly reports, and embrace the years 1904 and 1905. The light line shows the percentage of paludism and the heavy line

the percentage of cancer. The mortality from malignant disease, it will be observed, varies quite a little in the different communities, and yet an examination of the chart shows but little relation between this line and the fluctuations of the line for paludism. For instance, Puerto Padre, Manzanillo, Sancti Spiritus, and Cárdenas show the greatest malignant disease rates; yet in the first two the paludic rate is very high and in the last two it is relatively low. Consolación has the lowest malignant disease death rate and also one of the lowest paludic rates.

Chart No. 2 shows the percentage of the total death rate ascribed to paludism and malignant disease grouped by provinces for the entire island of Cuba for the year 1904. In this chart it will be observed that the province of Habana, with the lowest paludic death rate, and the province of Oriente, with the highest paludic death rate, have identical rates for malignant disease.

Chart No. 3 shows an interesting comparison between the malignant disease rate of Cuba and that of the New England States. The figures used for Cuba are the same provincial figures as used in the previous chart embracing the year 1904. The figures of the six New England States correspond to the year 1900, and were the only ones I had available for comparison. In both of them the figures are expressed in percentage of the total mortality.

A study of the mortality tables of the city of Santiago de Cuba, which has a fairly large morbidity and mortality rate from paludism, shows the following table of deaths from malignant disease and paludism in Santiago de Cuba for a period of sixteen months to include October, 1906:

	Natives		Foreign		
	White	Colored	White	Colored	
Paludism;	21.	60.	35.	2. (1, Hayti).	= 118.
Cancer, etc.	12.	35.	5.	3. (Martinique, Africa, China)	= 55.

Population of Santiago.—Native white.....15,711
Foreign white..... 3,458
Colored 26,309

45,478

The colored are not separated into native and foreign, because practically all those classed as foreign are from adjacent islands like Jamaica, Antiqua, etc., and are all tropical residents.

Annual ratio per thousand from malignant disease.. .916
Annual ratio per thousand from paludism..... 1.96

The following is a statement of the surgical work for malignant disease done in the General Hospital at Santiago during the eight years from 1899-1906:

All surgical operations..... 2,989
All major surgical operations over age 35..... 803
All major surgical operations for malignant disease.. 209

In the records of the hospital these patients are not classified by nationalities, but by color. Of the operations for malignant disease there were:

	White.	Mulatto.	Black.
Male	21	17	32
Female	36	66	37
Total	57	83	69

In the list of 803 major surgical operations on patients above the age 35, which has been assumed as the cancer age for this paper, all sorts of operations are included, such as special genitourinary operations, gynecological, and major obstetrical operations. This should be borne in mind when the figures are compared with other statistics where, under the head of operations, are only classed the usual operations of pathological surgery. In figuring up this list, however, all accident surgery, whatever its gravity, was excluded.

The special diagnoses of malignant disease as they appear in the records of the cases are as follows:

CASES CLASSED AS CARCINOMA.

Uterus	34
Uterus and vagina	4, 38
Breast	24
Stomach	6
Penis	5
Abdominal wall	2
Neck	2
Adenocarcinoma, Scarpa's triangle	2
Parotid gland	1
Face	1
Spermatic cord	1
Liver	1
Occipital region	1
Tibia (encephaloid)	1
Ovary	1
Hand	1
Kidney	1
Gall-bladder	1
Mesentery	1
Pancreas	1
Foot	1
Testicle	1
Carcinoma, iliac fossa	1
Groin	1
Vulva	1
	97

CASES CLASSED AS EPITHELIOMA, ETC.

Skin	17
Penis	10
Cervix	7
Mouth	6
Lip	4
Clitoris	1
Anus	1
Epitheliomatous degeneration of keloid	2
Malignant epulis	4
	52

CASES CLASSED AS SARCOMA.

Osteosarcoma of Femur	5
Lower jaw	5
Tibia	5
Humerus	3
Calcaneum	2
Foot	1
Finger	1
Malar bone	1-23
Uterus	2
Uterus and ovary	10, 12
Breast	5
Lymphosarcoma (not designated)	5
Fibrosarcoma (not designated)	5
Sarcoma Scarpa's triangle	2
Mesenteric	2
Eye	2
Carotid region	1
Face	1
Auricle	1
Angiosarcoma (supraclavicular)	1
	62

Grand total, 209

The following conclusions seem justified:

1. There is no real antagonism between malaria and malignant disease.

2. Malarial infection supervening on malignant disease does not modify the latter.

3. Natives of tropical countries enjoy a relative immunity to malignant disease, which, however, varies within wide limits.

4. The progress of civilization with the adoption of the ways of life of the white man materially diminish this immunity.

NOTES ON SIX THOUSAND CASES OF NEURASTHENIA.

By CHARLES D. CLEGHORN, M.D.,
NEW YORK.
CLINICAL ASSISTANT, DEPARTMENT NERVOUS DISEASES, VANDERBILT CLINIC.

Neurasthenia is the bête noire of the dispensary neurologist. This condition of affairs is easily understood. It arises from the fact that certain essential elements in the treatment of the disease are well nigh impossible for the average dispensary patient to undertake. Such patients cannot, as a rule, cease their work, nor alter it; they cannot change their surroundings; they cannot regulate their hours of sleep, nor can they often take rest enough, and their diet can seldom be much improved. The treatment of the disease by drugs is thus, to a large extent, made necessary, though it is far from satisfactory. In the following notes, therefore, no endeavor has been made to draw conclusions from methods of treatment at the clinic, but to present the facts obtainable regarding the patient and his illness prior to the introduction of treatment, *i.e.* history and symptomatology.

Before giving any figures let us recall a few of the classifications of neurasthenia advocated by different men. Nothing could well be more varied. To begin, Beard[1] divided cases into (1) cerebral, (2) spinal, (3) digestive, (4) sexual, (5) traumatic, (6) hysterical, (7) hemineurasthenic. Starr[2] says we can recognize cases as due to (1) anxiety and worry, (2) overexertion, mental or physical, (3) beginning degeneration of neurons, (4) toxic cases. Again, Starr[3] divides the cases anatomically into (1) general neurasthenia, affecting all parts of the nervous system and (2) local, involving brain or cord, or vasomotor system chiefly. Dana[4] gives the following forms: (1) primary, (2) hysterical, (3) acquired, (4) climacteric, (5) traumatic, (6) spinal, (7) with fixed ideas, (8) angiopathic, and (9) grave. Finally, Proust and Ballet[5] state as forms of neurasthenia (1) cerebrospinal, (2) neurasthenia of women, (3) genital, and (4) traumatic.

Out of 37,564 patients who have applied for treatment in the neurological department at Vanderbilt Clinic during the eighteen years from October, 1888, to November, 1906, there were found 6,000 cases of neurasthenia. From this list are excluded cases which had any definite symptoms recorded of hysteria or insanity. No cases in children under thirteen years of age were found which could not be attributed to the ordinary nervousness brought on by fright or poor environment, though some of them might have been found to be neurasthenic had they been followed up for a sufficient time.

Of the 6,000 cases thus remaining, 3,516, or 58.6 per cent., were male and 2,484, or 41.4 per cent. females. These figures correspond quite closely with those of Savill[6] and those of Collins and Phillips,[7] though differing widely from those of Von Hössling (see Table I).

TABLE I.

Showing Sex Ratio in Neurasthenia.

Reported by	No. Cases	Male	Per Cent.	Female	Per Cent.
Savill	127	77	61	50	39
Collins and Phillips	333	183	55	150	45
Von Hossling	828	604	72.9	224	27.1
Cleghorn	6,000	3,516	58.6	2,484	41.4
Totals	7,288	4,380	60.9	2,908	39.9

Proust and Ballet[5] and Starr[3] state that the disease is more frequent in men, but they give no figures. Savill[6] says it occurs equally in the sexes, but his figures do not bear out this statement (see above).

The civil state of the cases in our series shows, as would be imagined, that the percentages of married and single patients are almost equal. Table II. gives the findings of Collins and Phillips compared with our own.

TABLE II.

Showing Civil State Ratio in Neurasthenia.

Reported by	Sex	Single	Married	Widowed
		Per Cent.	Per Cent.	Per Cent
Collins and Phillips	Male	20	29	.....
	Female	14	31	.....
Cleghorn	Male	31.3	24.2	.9
	Female	14.1	25.7	3.8

Neurasthenia occurs most frequently in the early years of maturity, a time when the organism should be strongest in repelling disease of mind or body, but a time when one is subjected usually to the greatest mental and physical strain. The part this plays as an etiological factor will be considered later. Our figures show a very large percentage of men affected between the ages of 20 and 30 years. This disproportion is explained by the frequency of the sexual type in men at that period of life, about 80 per cent. of sexual neurasthenias occurring in the third decade. Even omitting these cases, the third decade would remain on an equal footing with the fourth in its production of neurasthenia. The oldest case we found recorded was in a woman seventy-five years of age; the youngest, as stated above, was thirteen, at which age three girls were recorded. Table III. gives the numbers and percentages of our cases by decades compared with the percentages given by Collins and Phillips.

TABLE III.

Showing Ages of Neurasthenics by Decades.

Decade	Cleghorn			Collins & Phillips
	Male	Female	Per Cent.	Per Cent.
10-20	242	162	6.7	6.6
20-30	1,542	822	30.4	30.6
30-40	1,002	815	30.3	27
40-50	481	370	14.2	16.2
50-60	172	244	7	8.4
60-70	55	60	1.9	2.1
Above 70	3	0	.1*	†

*Age not reported in 24 cases.
†First decade not shown.

Natives of the United States, of course, predominate among the applicants for treatment at the clinics in New York. In our statistics due allowance must therefore be made for this fact. Russians and Poles are said to have a susceptibility for neurasthenia, but no statistics were found referable to the disease in Russia. Natives of that country formed 10 per cent. of our series, while Collins and Phillips had 20 per cent. among their 333 cases.

TABLE IV.

Nativity Percentages.

Birthplace	Cleghorn	Collins and Phillips
	Per Cent	Per Cent.
United States	48.7	43.5
Ireland	16.5	16.2
Russia	10.0	20.7
Germany	8.5	10.2
England and Canada	6.3	2.4
Austria	3.2	4.5
Hungary	1.1	.....
Italy	1.3	.....
Sweden	1.2	.....
France	0.6	0.6
Scattering	1.7	7.6

Occupation in its relation to neurasthenia has been the subject of much discussion. According to Starr[3] the disease is more frequent among the highly educated classes than among manual workers, and this view is borne out by Von Hössling's[8] report (q.v.). This distinction, however, is not available in dispensary work. Here we can compare only active with sedentary and indoor work. We found 2,063 cases occurring among persons engaged in the principal indoor occupations, *i.e.* housework, domestic service, sewing, tailoring, factory work, machine operating, clerking, studying, storekeeping etc. On the other hand, the active and outdoor workers, drivers, laborers, porters, waiters, carpenters, painters, firemen, watchmen, and railroad workers, yielded only 1,053, or about one-half as many cases. This would seem to be a strong piece of evidence toward proving the sedentary occupations a predisposing cause of neurasthenia. Table V. shows occupations as we found them, omitting the unimportant ones. Von Hössling's[8] table and one from Collins and Phillips[7] are also given.

TABLE V

Cleghorn.

Occupation	No.	Occupation	No.
Housework	542	Salespersons	92
Clerks	340	Agents	90
Laborers	297	Porters	85
Tailors	286	Printers	86

Indoor Work	264

The etiological factors in neurasthenia are so many and so varied that they must be classified in some way, in order to simplify them. After dividing them into the predisposing and the exciting causes, hardly any two men use the same classification. Starr[3] gives heredity as the predisposing cause "par excellence," and as exciting causes (1) mental strain and worry, (2) alcoholic and sexual excess, (3) disease, (4) shock and anxiety, (5) sudden change in life habits, (6) genital disorders, especially in women, (7) reflex irritation, (8) poisons from imperfect metabolism, (9) injury, (10) fright. Savill[6] gives as predisposing causes (1) heredity, (2) sedentary occupation and indoor life, (3) general malnutrition, and as exciting causes (1) overwork, (2) alcohol, (3) masturbation, (4) long-continued pain, (5) dyspepsia, (6) constipation, (7) Graves' disease, (8) Glénard's disease, (9) illness, (10) grief, (11) eyestrain, (12) trauma, (13) drugs, (14) insomnia, (15) poor teeth.

Proust and Ballet[5] mention as special causes (1) heredity and (2) defective education, and as exciting causes (1) excessive brain work, (2) pressure in school, (3) moral overpressure, (4) intoxications, (5) disease, (6) trauma, (7) fright, (8) dyspepsia, (9) genital disorders.

Beard[1] said the fundamental causes were (1) mental labor and overstrain, (2) derangement of nutrition.

Drowse[9] places great stress on heredity, and says "the fundamental cause of neurasthenia is a want of correlative integrity between cerebrospinal and sympathetic centers."

Abrams[10] gives as causes (1) overwork, (2) worry, (3) alcohol, tea, and coffee, (4) syphilis, (5) illness, (6) trauma, (7) puberty, (8) genital disorders. Glénard gave enteroptosis as the cause. Dunin[11] stated that many cases were due to constipation, and Federn[12] thought that most cases had an intestinal origin. Collins and Phillips[7] had in their series as causative factors (1) overwork in 27 cases, (2) masturbation in 26, (3) worry in 18, (4) childbirth in 12, (5) sorrow in 11, (6) fright in 10, (7) trauma in 8, (8) disease in 7, (9) alcohol in 4.

A definite etiological factor was recorded in 1,793 cases in this series, or, if we include constipation as a cause, in about 3,000 cases. Should we also add to this list cases which gave dyspepsia as a most prominent symptom (according to Savill, and Proust and Ballet), we would have some hundreds more. The exact figures, however, cannot be had, as many patients gave constipation or dyspepsia as a symptom after stating some more generally recognized cause. The heredity of patients in our series unfortunately was not obtainable, as it was recorded in but a few instances. In the table showing etiological factors, the list is modeled after that given by Church and Peterson,[13] which is followed quite closely.

TABLE VIII.

Showing Etiology in Neurasthenia.

Etiology	Male	Female	Total
Heredity, Neuropathic	30	20	50
Heredity, Cachexias	3	7	10
Overwork and Worry	90	119	209
Alcoholism	343	87	430
Tea and Coffee excess	29	192	221
Trauma	115	61	176
Post-operative	29	52	81
Illness	58	75	133
Toxic States	69	8	77
Shock	48	150	198
Menopause		90	90
Miscarriage		83	83
Pregnancy		35	35

In the above table the toxic cases consist of five cases of lead poisoning and seventy-two cases of probable nicotine poisoning. The heading, overwork and worry, covers both mental and physical

overstrain, also worry or anxiety over family or business troubles. From the figures, excess in alcohol among the men, and in tea and coffee among the women, stand out as frequent causative factors. Together they form 33 per cent. of the whole list. Overwork and worry also play a prominent part, and in this class were found many of the fifty-one students recorded. It is of interest to note here that Nesteroff[14] found neurasthenic symptoms present in 30 per cent. of 588 pupils examined by him, the percentages increasing from a minimum in the young classes to a maximum near graduation. Illness, finally, as remarked by most men, is one of the chief causes of nervous exhaustion, and was a factor in 133 cases of our series.

Symptoms will be given in the order they are named by Church and Peterson, no other list apparently suiting all conditions so well. First, then, let us consider motor disorders. Tremors were noted in 1,087 cases and muscular twitchings in 166; weakness was complained of by 742 patients. The reflexes were recorded as exaggerated in 340 and decreased in 54 cases.

Among the sensory disturbances, headache was the principal symptom. It occurred in 1,935 instances (for subdivision see Table IX). Paresthesias were present in 434, dizziness in 560, and backache in 518. The vague sensations of indefinite character, which could not be classified, were rather constant, being found in 705 persons. Disorders of sight and hearing were not common.

The alimentary tract gave rise to the symptoms most frequently met with, as follows: Poor appetite in 898 cases, constipation in 1,499, and diarrhea in 90, gastric flatulence in 387, pain in the region of the stomach in 297.

The circulatory system showed cardiac palpitation in 479 patients, and vasomotor disturbance in 429.

Among mental symptoms emotional irritability was the most frequent, occurring in 550 cases. Then followed worry in 444, various fears in 351, and poor memory in 338. Insomnia, next to headache, was the most constant symptom found, being complained of by 1,684, almost equally divided between males (879) and females (805). Depression was noted 599 times. The complete figures and approximate percentages follow:

TABLE IX.

Symptoms in Neurasthenia.

Symptoms	No.	Per C't.	Symptoms	No.	Per C't.

* Patients whose symptoms included constipation and headache with unrecorded location were put in Frontal Headache class.

The various symptoms, in order of frequency as we found them, compared with the lists given by Savill[6] and by Collins and Phillips,[7] may be of interest. They are shown below:

TABLE X.

Symptoms in Order of Frequency

Savill	Collins and Phillips	Cleghorn
Fatigue easily	Insomnia	Headache
Headache	Headache	Insomnia
Insomnia	Constipation	Constipation
Restlessness	Palpitation	Tremors
Pain in back and legs	Poor appetite	Poor appetite
Emotional, Irritable	Indigestion	Weakness
Timidity	Vertigo	Vague Sensations
Poor memory	Backache	Depression
No capacity for Cerebration	Hot flashes	Dizziness
Sighing and Yawning	Epigastric pain	Emotional irritability
Rapid Pulse		Anemia
Vertigo		Backache
Gastric Symptoms		Palpitation

One type of neurasthenia is still to be spoken about, namely, the sexual. This occurred in 839 cases out of 6,000, including 5 females. Loss of sexual power was shown in only 185, while 525 cases gave a history of masturbation.

TABLE XI.

Sexual Neurasthenia.

	Male	Female	Total
Sexual excess	196	3	199
Loss of power	184	13	185
Nocturnal emissions	462	.....	462
Masturbation	518	7	525
Pain in genitals	18	.....	18

Were it possible to make a careful study of each case among these 6,000, no doubt some would be found whose symptoms were caused by a pathological condition which was undiscovered. Some of the records of these cases were somewhat lacking in completeness, but they seem sufficiently definite to warrant certain conclusions of value about the disease.

To summarize the facts most clearly brought out:

1. Neurasthenia is much more frequent in men than in women.

2. It occurs between the ages of 20 and 40 in two-thirds of the cases, few comparatively starting after 40.

3. The indoor occupations furnish a large majority of all cases.

4. Among causative factors, the disturbances of the gastrointestinal tract and the intoxications stand out as principals, and

5. The most constantly present symptoms seem to be headache, insomnia, and constipation.

Is this last-mentioned condition really a cause or a result of the disease? I wish very much that more information on this point might be brought to light.

PATHOLOGY OF GONORRHEA IN WOMEN.*

BY H. C. COE, M.D.,
NEW YORK.

I RECALL an eloquent tribute paid by my reverend teacher, Dr. Oliver Wendell Holmes, to his colleague, Dr. James Jackson, the ancient Professor of Pathological Anatomy, who, unaided by the microscope, had attained a knowledge of his subject far in advance of his generation. With a similar admiration do we reread the classical paper of Dr. Noeggerath, who thirty years ago, with an imperfect knowledge of pelvic pathology and no inkling of the future achievements of bacteriology, had what now seems to be a prophetic vision of the results of the infection which claims out attention this evening. Few of those present can recall the incredulity with which his advanced views on "latent gonorrhea" were received, but all admit that he was the pioneer in this field of investigation. Like Sims, he sketched in outline a picture which those who followed him have gradually filled out in detail. In my student days gonorrhea was regarded as a trivial local affection, transient in its course, and easily cured. The medical student of to-day is taught to regard it as even more serious than syphilis, especially in the female. His familiarity with its results, as seen at the operating table, is a more forcible object lesson than could be furnished by any lecturer or text-book.

The brief time allotted to me forbids my discussing the more elementary points in pathology, which I assume are known to you, so that I shall devote my attention to the more recent investigations of the intrapelvic lesions in the female as they are seen by the surgeon. The old views as to the site of primary infection have been considerably modified. It was formerly held that the vagina was first infected, but we now know that the intact mucosa of this canal is quite resistant to the action of the gonococcus, and that the germ may enter the cervix at the time of the impure coitus, with or without accompanying infection of the urethra, Bartholinian glands, or vulva. Moreover, it is a fact often noted that the most virulent specific vaginitis may not extend beyond the cervical canal. It has never been satisfactorily explained why such extensive changes in the tubes should result from an infection apparently so mild that its inception was not noticed by the patient, or why a severe type should remain localized below the *os internum*. Doubtless the different powers of resistance in the tissues of different individuals accounts for this irregularity. Certain it is that gonorrheal infection assumes protean forms, as is known to surgeons who have operated during all stages of the disease.

It has been demonstrated beyond a doubt that the mere presence of Neisser's cocci in the secretion does not account for all the tissue changes that occur. They possess toxic properties which are active after the microorganisms themselves have perished. Bacteriologists are familiar with the frequent occurrence of mixed infection, and it is probable that the *Staphylococcus aureus* and colon bacillus remain active after the gonococci have disappeared. "Latent gonorrhea" is observed in the female as well as in the male, small foci of infection again spreading under the influence of pregnancy and the puerperium, or even in consequence of the menstrual congestion. It is customary to regard gonorrheal infection as superficial, rarely penetrating the subepithelial layer, and extending only by continuity to the tubal mucosa, thus offering a sharp contrast to the more profound and far-reaching effects of the streptococcus; but it has been shown conclusively that the muscular wall of the uterus may be invaded, and that lymphatic infection does occasionally occur in the specific form of inflammation, as well as in the septic. Gonorrheal cellulitis, like gonorrheal rheumatism, is rare in the female, and is probably due to mixed infection.

So far as my personal observation goes, I am inclined to doubt that the stroma of the ovary is primarily affected by way of the lymph-channels, as in septic oöphoritis, and there is no reason to believe that the *intact* cortical zone is easily infected secondary to specific salpingitis. In my opinion, the acute oöphoritis in this connection is more often due to mixed infection, while hyperplastic and cystic degeneration are rather the result of interference with the normal circulation in consequence of surrounding exudates. It is common to enucleate from a mass of adhesions a normal ovary, which can be safely spared when the tube is hopelessly diseased.

The subject of diffuse gonorrheal peritonitis has awakened much interest of late, several cases having been recorded which are explained by the theory of lymphatic infection. Most of those have been operated upon successfully, in striking contrast to the virulent character of diffuse septic peritonitis. Fortunately, Nature's protective power is shown in the majority of these cases by the localized inflammation which confines the focus of infection to the pelvis. Intraperitoneal rupture of a pus tube I have never observed. It must be most rare. The opportunities for studying the various types of gonorrheal affection in the female in Bellevue Hospital are probably unsurpassed. The routine bacteriological examination of vaginal discharges and of the contents of tubal and ovarian abscesses has developed many interesting facts, the most important practical result being the conclusion that irrigation and drainage are seldom necessary. Until recently abdominal surgeons prided themselves on saving many patients by this practice. Now we see that they recovered in spite of those measures. Why? Because in the majority of the cases either the pus was sterile, or the focus of infection was entirely removed at the time of operation.

Lack of time forbids my entering into details. It suffices to state that we have found in pus every variety of microorganism (except the pneumococcus, which has been found by other observers) associated with the gonococcus; that in patients with an acute gonorrheal vaginitis and urethritis the contents of diseased tubes has often proved to be sterile, although signs of a recent attack of peritonitis were present. In other cases where there was no evidence of vaginal or uterine infection, such an acute inflammation has been found within the pelvis and abdomen that in several instances it could be fairly charac-

*Read at a meeting of the Medical Society of the County of New York, March 25, 1907.

terized as a hemorrhagic peritonitis—in fact, they were supposed to be cases of ruptured ectopic on account of the amount of free blood, until a careful examination of the tubes showed that they were the seat of an intense gonorrheal inflammation. These facts are hard to explain, except on the supposition that the infection may actually skip the vaginal and uterine mucosæ to expend its action on the tubes.

The type of gonorrheal inflammation encountered by the surgeon is rarely of the acute type. It goes without saying that the presence of sactosalpinx, greatly thickened tubes, and dense adhesions implies a long-standing process. This applies even to those cases (such as one that I encountered to-day) in which, with an acute gonorrheal endometritis, the patient had an old inflammatory condition of the adnexa of undoubted specific origin. I have removed half a dozen tubes, the seat of intense salpingitis, the anatomical appearance corresponding to the history of acute infection, where Neisser's coccus was found in large numbers in the pus squeezed from the distal ends of the tubes. Conservative operations were performed in most instances, and no febrile reaction followed. The operation was not done intentionally, for I do not feel that there is sufficient warrant to either curette the endometrium during the acute stage of gonorrheal infection, or to remove such tubes as I have described.

Although so fond of the urethral glands, fortunately gonorrheal infection rarely extends to the bladder, and still more infrequent is ascending ureteritis and specific inflammation of the renal pelvis. The danger of interfering with Nature's barrier at the sphincter vesicæ has been shown in instances in which infection has occurred as the result of endoscopic examinations and catheterization.

Attention has been called to the susceptibility of the puerperal uterus to gonococcus infection. In a sad case of this sort, in which impure coitus occurred a day or two before delivery the symptoms were so acute as to be mistaken for those of perforative peritonitis. I operated on the fifth day, but too late to save the patient. The appendix was normal; both tubes were intensely congested and filled with pus, and there was a diffuse peritonitis. No adhesions were present. The infant had severe gonorrheal ophthalmia.

I have called attention in previous papers to the frequent association of appendicitis with tubo-ovarian disease. This is doubtless nearly always secondary to the perisalpingitis attending gonorrheal pyosalpinx, and not to specific infection.

All surgeons are familiar with the various forms of adhesions and exudates found at the operating table, especially the extensive intestinal form, which may render the enucleation of pus tubes so formidable to the inexperienced.

The interesting questions suggest themselves: Do such exudates disappear spontaneously or under palliative measures and if so, why? Is a *restitutio in integrum* possible in the case of a tube, the mucosa of which has been destroyed by gonorrheal infection? Can a pyosalpinx discharge itself into the uterine cavity? To what extent is a previous salpingitis an etiological factor in the causation of tubal gestation? Is "latent gonorrhea" the principal cause of sterility, as Noeggerath originally claimed? I regret that I cannot discuss these at length, but can only state briefly the results of my own observation.

There is no question that under the influence of rest, hot douches, and boroglyceride or ichthyol tampons the most extensive exudates do disappear (probably through lymphatic absorption), leaving the diseased tubes clearly outlined, where before they were indistinguishable, and that a symptomatic cure is obtained. I do not believe, from my experience both as a pathologist and a surgeon, that a tube once thoroughly diseased is ever restored to its previous normal condition. There is no question that the mucosa may be regenerated after exfoliation, but the ends of the tubes are nearly always agglutinated, so that sterility is inevitable. Clinical evidence alone does not convince me to the contrary.

I have never been able to satisfy myself, either clinically or from examinations of hundreds of pus tubes, that their contents can be spontaneously discharged into the uterus. Patients in whom this has been said to occur I have afterward operated upon, and have demonstrated its impossibility.

I think that too much stress has been laid upon the importance of gonorrheal salpingitis as a cause of arrest of the impregnated ovum in the tube, since the distal end is usually sealed up as the result of the disease. It is difficult to imagine a gonorrheal inflammation that has been arrested at the inner or middle third, leaving the outer third untouched. The old question of the frequency of "latent gonorrhea" in the male, as a cause of infection of the tubes and resulting sterility, must be answered with some qualifications. Since it has become the practice to pay more attention to the matter of azoöspermia in the husband before treating the wife for sterility, we have doubtless concluded that Noeggerath's percentage was rather too high, and that occlusion of the seminal ducts, as well as of the tubes, plays an important part in this question.

GONORRHEA IN WOMEN.*

INFECTION OF THE URETHRA, VAGINA, AND DUCTS OF THE GLANDS OF BARTHOLIN.

By WILLIAM S. STONE, M.D.,

NEW YORK.

The frequency of gonorrheal infection in women, and the opportunity thus afforded for every general practitioner to observe its clinical relations, would almost seem to render the present discussion of the disease unnecessary. The great importance, however, of the disease to the community, and the erroneous impressions that are still prevalent about some of its manifestations, may furnish the reason for its discussion at this time. This is especially true of the lesions of the external genital organs, the consideration of which has, perhaps, been somewhat neglected on account of the keen attention that has been directed toward the surgical treatment of the results of this infection in the internal organs. The infections of the external genitals also, representing as they usually do the early and more acute stages of the disease, are often not observed by the physician because of the frequently transitory nature of the subjective symptoms and of the erroneous significance which the patients themselves ascribe to their presence.

The writer's share in the evening's discussion will, perhaps, be best performed (1) by briefly referring to some of the features observed in his own experience, mentioning particularly some of the prevalent impressions that seem to him to be erroneous, and (2) by pointing out the practical value these lesions

*Read at a meeting of the Medical Society of the County of New York, March 25, 1907.

may have for the physician in the way of diagnosis and treatment.

The Urethra.—The common idea that the urethra rarely escapes being involved early in the course of the disease the writer believes to be true, although functional disturbances of the bladder from other causes are so frequent in women that the physician is often not consulted until the urethritis is better or well. On account of the shortness of the female urethra, its entire length is usually involved, but the course of the disease is usually milder and of shorter duration than in the male. It is the experience of the writer that, with appropriate treatment, the disease lasts only from four to six weeks, but that without treatment the involvement of Skene's ducts occurs in a large number of cases, thus persisting as a local complication for an indefinite period of time. On account of the early involvement of the entire length of the canal, frequency of urination and more or less vesical tenesmus are rarely absent, giving rise to the common expression "gonorrheal cystitis." Whenever the writer hears this expression used he wonders whether it is from ignorance or carelessness, because the truth of the matter is that, with the exception of a congestion at the vesical neck, gonorrheal cystitis rarely occurs, and the ascent of the infection to the ureters, as reported by Kelly, is the rarest of all complications. Chronic gonorrheal urethritis frequently occurs, usually, however, as a local condition in or about Skene's ducts. Stricture of the female urethra as a result of this disease the writer has only observed once in an experience of over twelve years at Vanderbilt Clinic. Suburethral abscess, as a result, has been noted by the writer three times. Based upon his observation of the natural course of the disease, the writer's treatment has consisted (1) in proper instructions relative to diet and the contagiousness of the disease; (2) in copious draughts of plain water and such internal medication as will render the urine bland, of which the tincture of hyoscyamus and the bicarbonate of potassium have been as efficient as any; (3) in the applications of heat to the external genitals, preferably by means of hot sitz baths, and (4), the most important of all, in frequent cleansing of the external genitals with plain or mildly antiseptic solutions, in order to prevent infection of Skene's ducts and the ducts of the Bartholinian glands. Injections in the acute form of the disease the writer believes are unnecessary and perhaps harmful. The writer's general conclusion in regard to the disease in the female urethra, then, is that it is usually less important than in the male, the chief thing being the frequent involvement of Skene's ducts whereby reinfection of other parts is always liable to occur, and the constant danger of the transmission of the disease to others.

The Vagina.—The most frequent misapplication of terms is the expression "gonorrheal vaginitis," as applied to the presence of the infection in adults. The absence of glands and the character of the vaginal epithelium render this part of the genital tract comparatively invulnerable to the invasion of the gonococcus, except in young girls before puberty, in adult women during pregnancy and the puerperium, and in elderly women at the time of the menopause. A redness and irritation from the stagnation of gonorrheal discharges from the uterus often occurs, but a few douches with a mildly antiseptic solution quickly clears it up. The writer at this time will only emphasize the importance of its early recognition and treatment as representing the chief lesion in young girls before puberty. It is commonly taught that, on account of the rudimentary condition of the uterus and adnexa at this period of life, these organs are rarely involved, but the reports of cases of obscure peritonitis in female children are rapidly accumulating, so that this observation may not be so true as it was once thought to be. In two cases of young women who have presented a chronic uterine discharge, with genital organs resembling those of women at the menopause, the writer was able to trace the course of the disease directly back to a gonorrheal infection in childhood.

In elderly women whose history shows that a gonorrheal endometritis has existed for a long time the atrophic changes incident to the age of the patient will be often seen associated with a very profuse and purulent discharge containing gonococci, often also in conjunction with an acute purulent urethritis. There is no doubt in the writer's mind that these atrophic changes are important factors in the lighting up of an old gonorrhea with a reinfection of the urethra. The vaginal mucosa, however, in its normal condition, should be considered as comparatively invulnerable to this infection, and to act upon the belief that treatment directed exclusively to this part of the genital tract will eradicate the disease can only lead to grave disaster. It should also be remembered that the taking of the vaginal discharge alone for a microscopic diagnosis of the disease will often lead to error.

The Ducts of Bartholin's Gland.—The common mistake of regarding the glands themselves as the seat of the disease is illustrated by the printed program for this evening, as the infection is usually limited to the ducts, and whenever the glands are involved it is generally regarded as a mixed infection. The infection of these ducts is considerably less frequent than that of the urethra, and usually occurs later in the disease. It is the result, probably, in most instances of the stagnation of gonorrheal discharges about the genitals, and thus is largely preventable. The smallness of the opening undoubtedly accounts for their escape in a certain number of cases, for in children in which the opening is very small the ducts are almost never involved. The swelling of the duct from the retention of pus in the closed duct is well known to all. Not infrequently, however, if seen early, the opening is still patent, and pus may be pressed out, and by daily milking its closure may be prevented until the inflammation has disappeared. I know of no way of treating the inflammation in the duct itself except by incision and drainage.

The Diagnostic Value of These Lesions to the Physician.—It has been the custom of the writer for a number of years to teach that as a matter of routine the external genitals should be inspected and palpated before the vaginal examination is made, interpreting the following as evidences of a previous or recent gonorrhea; the swelling of a Bartholinian duct, the presence of a purulent discharge from the opening, the presence of reddened patches about the orifice (the macula gonorrhoica of Sänger). Although as shown by Krönig and Menge, and others, infection of these ducts in exceptional instances may be due to the staphylococcus or other bacteria, the gonococcus is the causative agent, in almost all cases. The presence of pus in the urethra is given the same interpretation as it is in the male. In order to detect the presence of pus in the urethra, a certain technique in the examination must be followed. The meatus must be first wiped perfectly clean in order not to mistake discharges that may be present about the vestibule for urethral pus. With one finger in the vagina the urethra is milked from the vesical

neck downwards to the meatus. The pressure against the urethra must be continued down to the very edge of the meatus, the latter part of the pressure being made against the anterior surface of the symphysis. It is only in this way that discharges retained in Skene's ducts will be expressed, it frequently appearing on either side of the urethra at the very last moment. The frequency with which pus may be expressed from these ducts may be concluded from the fact that in fifty clinic cases recently examined by the writer, pus or muco-pus was present in thirty-six. In regard to the information that the presence of these lesions may give, the writer wishes to call attention to one particular class of case, which is often seen in any large clinic, namely, the patients applying for relief of sterility. In many of these cases the uteri have been previously dilated and curetted, and among them are not a few with symptoms that they did not have previous to their operation. The examination will disclose the presence of inflammatory diseases of the adnexa which, from their history, there is every reason to believe followed their operations. The signs of an old gonorrhea will also be found about the external genitals; usually pus can be expressed from Skene's ducts. The writer has made this observation so many times now that he always points out to the students the significance of these signs about the external genitals, and teaches them that, although the uterus may be of that type in which operative procedures are often of value, yet with the presence of pus in the urethra, for example, all operative measures are contraindicated.

In conclusion, the writer would call special attention to the value of these signs of gonorrhea as aids in the diagnosis and treatment of diseases of the female genital organs.

41 West Seventy-first Street.

GONORRHEA DURING PREGNANCY.*

By J. CLIFTON EDGAR, M.D.,

NEW YORK

The time limit of ten minutes allowed for the presentation of this important subject of necessity compels one to confine his remarks to the more prominent facts only regarding gestational gonorrhea.

Few observations have heretofore been made on the subject; in fact, so little work has been done upon both pregnancy and puerperal gonorrhea that there are some who deny the existence of a gonorrheal morbidity or mortality in pregnancy and the puerperium. The difficulty in recognizing the gonococcus has undoubtedly favored this belief.

It is in private practice particularly that our most valuable and reliable information can be obtained upon this subject, because here one often can observe the course of the disease from infection through pregnancy, during labor, and until the termination of the puerperium.

The average case in a maternity hospital is seen possibly once before confinement, and often not until labor actually sets in. Then, again, patients of the lower class can rarely be prevailed upon to remain more than ten days in the hospital after confinement, unless actually bed-ridden, so that observations and statistics of this class of patients must naturally be looked upon with discredit. To be sure, the difficulty of getting patients to speak the truth in such matters as vaginal infection applies to both classes of patients, but this difficulty is largely counterbalanced in private practice by reason that the patient is more often seen, and can usually be kept under observation from start to finish.

Even accepting, for the sake of argument, the statement of Blaschko, claiming that every man who does not marry until the age of thirty, has had gonorrhea twice, or that of Ricord, that the percentage of males who contract gonorrhea is over eighty, or the recent one of Erb[1] that about forty-nine per cent. of men have gonorrhea before marriage, most of them contracting it before the age of twenty-five. Accepting these figures as within the bounds of truth, still my observation leads me to take a rather optimistic view of the effects of gonorrheal infection upon the pregnant woman. By this I mean those instances in which infection has occurred either during pregnancy or just prior to impregnation, or during the act of conception itself. I do not wish to be understood as belittling the importance of the gonococcus as a causative factor in the production of endometritis and subsequent abortion, salpingitis, pelvic inflammation, a stormy or even a fatal puerperium, and one-child sterility, but simply that women who contract gonorrhea during pregnancy do not necessarily suffer as far as the pregnancy is concerned. Indeed, it would appear that invasion of the uterine cavity by the gonococcus during pregnancy is less likely to occur than in the nonpregnant state. To be sure, the gonococcus has been demonstrated in decidual endometritis in a limited number of cases by Neumann, Maslovsky, Williams, and others. Again, in a still more limited number of instances, the gonococcus is said to obtain access to the liquor amnii, causing antepartum gonorrheal ophthalmia in the fetus.

Armarguac[2] is authority for one case of prenatal gonorrheal ophthalmia, and Nieden[3] reports an instance in which the fetus was born with a caul, and when liberated from the membranes was found to have gonorrheal conjunctivitis. Such cases could hardly occur unless a gonorrheal endometritis or deciduitis had previously existed.

Wintersteiner's analysis[4] of 122 cases of actual ophthalmia neonatorum includes two instances of antepartum infection of the fetal eyes.

A glance at the literature of gestational gonorrhea will readily demonstrate a wide diversity of opinion upon the subject.

It was Sänger's belief that gonococci continue to thrive during gestation. He has seen them in various localities. One claim of his is that gestation is seldom interfered with, which is controverted by some of his colleagues.

Frühenholz also denies that the gonococcus is militant against pregnancy. For him gonorrhea in early gestation is a reawakened focus. On the other hand Audebers claims that gonorrhea interrupts pregnancy in two out of three cases.

Fehling calls attention to the fact that conception and contraction of gonorrhea are prone to occur at the same time. He believes under such circumstances that the cocci may reach the tubes before labor.

Steinbuchel studied 328 pregnancies to determine the frequency of gonorrhea. He found the cocci present in 70 in the secretions, but, notwithstanding, but three cases of puerperal gonorrhea resulted. Conversely Krönig found that of 296 cases of puerperal fever, 31 had antecedent gonorrheal endometritis.

Bumm thinks that gonorrhea is spontaneously healed late in pregnancy, as far as the disappearance of cocci from the secretions is concerned. But he believes that the said germs persist alive in the endo-

*Read at a meeting of the Medical Society of the County of New York, March 25, 1907.

cervical glands, and may be roused to activity at labor. Wertheim's views are the same.

The fact that gonorrheal infection of pregnancy is often apparently mild in character, and frequently fails to attract attention by reason of the absence of endometritis, tubal involvement, and pelvic inflammation, is liable to deceive the patient and her physician, into a position of false security. Treatment of the condition is desultory or neglected, and all too late the true seriousness of the infection is realized at labor and the puerperium, by reason of a gonorrheal ophthalmia of the infant and an extension of the infection into the uterus, tubes, and pelvic peritoneum of the mother.

The most severe case of gonorrheal ophthalmia I ever saw in private practice was in the instance of a patient who married in January, and whose husband subsequently confessed to me that he suffered from acute gonorrhea the previous August. The presence of gonorrheal infection in this patient was unsuspected during pregnancy, as her only symptom was a persistent leucorrheal discharge which she attributed to her pregnant condition, and for which she did not consult her physician. In another instance, gonorrheal infection of the glands of Bartholin resulted during the latter part of pregnancy in little if any systemic disturbance, but immediately after delivery the symptoms of pelvic infection became marked, general systemic infection followed, and death occurred ten days post partum.

A serious sequela of gestational gonorrhea, and one which, so far as I know, has received little if any attention, is the effect of several months' insidious endocervicitis of gonorrheal origin upon the tissues of the cervix and lower uterine segment. In several of my cases in private practice I can explain the prolonged and difficult dilatation of the os on no other grounds.

I am of the opinion that the teaching of Bumm and Krönig, which held that the vaginal mucus possessed a bactericidal action, has done more harm than good, because it has been widely misunderstood and generally applied to gonococcus infection. The vaginal mucus has never been proven to possess such an antagonism to the gonococcus. If we accept the frequency of gonorrheal infection in the male as laid down by Blaschko, Ricord, and Erb, as only approximately correct, then it must follow that the same infection in the female is more frequent than is generally accepted. It certainly, in my experience, is commonly met with in private practice. And if this be true, and moreover if it be true that gonorrhea in pregnancy is often overlooked by reason of the absence of uterine and parauterine, and periuterine conditions, then the tendency to consider the pregnant vagina sterile in most instances is dangerous and liable to increase the morbidity of the puerperium, and the cases of ophthalmia neonatorum.

The Differential Diagnosis Between Acute Appendicitis and Acute Salpingitis.—The sudden acute onset of abdominal pain with tenderness over the appendix region, but with rigidity of the right rectus low down, is very suggestive of acute salpingitis. The diagnosis is further confirmed if there is high temperature and extremely hgh leucocyte count (20,000-40,000; polynuclears, 80-90 per cent.), even though vaginal examination be negative.—*American Journal of Surgery.*

THE EYE AND EAR COMPLICATIONS OF INFLUENZA.*

By CHARLES GRAEF, M.D.,

NEW YORK.

As influenza is an acute, infectious disease, one may expect it to present eye and ear affections of a type common to other diseases of this class. As it is an infectious disease with a markedly catarrhal tendency, its effects are most marked on the mucous membrane portions of these organs. When we remember the vast numbers of persons commonly affected in any epidemic of influenza, it is proper to add, however, that eye complications are comparatively infrequent. The initial coryza common with many patients is accompanied by hyperemia of the conjunctiva. It is hardly a complication, and should be rather regarded as a *symptom* of the disease. It is an *irritation* of this mucous membrane—not an inflammation.

Conjunctivitis with mucous or mucopurulent secretion, is much less common and severe cases occur but rarely. Croupous, and even diphtheritic forms of conjunctivitis have been observed as a sequence of influenza, but are not properly classed as a complication of this disease. Endemic outbreaks of catarrhal conjunctivitis, commonly known as "pink eye," sometimes occur with or soon after the appearance of influenza in a community. Such an outbreak is a coincidence, rather than a matter of cause and effect. Sometimes edema of the conjunctiva and swelling of the lids are seen, and hordeola or styes are quite common.

Conjunctival hemorrhages occur at times in influenza patients, and are produced by purely mechanical means through severe spasms of coughing and sneezing. This is especially likely to happen in older persons, whose vessels have brittle walls.

Inflammations of the tear duct are caused at times by the infection of the membrane lining this passage, and in patients liable to such troubles, outbreaks of dacryocystitis are easily produced.

Influenza patients suffer quite often with eruptions of *herpes*. On the lips this occurs in as many as 25 per cent. of all cases. Similar eruptions occur quite frequently on the lids and cornea, and breaking open are likely to end in ulcers of a more or less troublesome form.

Aching pain about the eyes, with tenderness on pressure and on movement of the globe, is often complained of. These pains are more often due to inflammation and swelling of the mucous membrane lining the frontal sinuses and other cavities about the orbit, than to any affection of the eyes themselves.

More serious affections of the eyes, due to influenza occur, but it is pleasing to note that the more serious the complication the less often it is seen. Many of these, too, are due to embolic processes and are caused by mixed infections—staphylococci, streptococci, and the pneumococcus being most often responsible (Knies). Inflammations of the iris and of the connective tissue coats of the eye are among the rarer occurrences. I have seen recently several cases of iritis, in rheumatic persons, in whom the outbreak was very evidently due to an attack of influenza.

The occasional occurrence of acute glaucoma in persons disposed to this serious disease, following infection by the influenza poison, should not be for-

*Contributed to a symposium on influenza before the Bronx Medical Association, March 28, 1907.

gotten. The severe headache of influenza easily disguises the similar pains due to glaucoma, and the confusion of these causes may easily end in loss of sight. Any patient suffering from influenza and having a persistent headache which does not yield to the usual sedatives should prompt a careful examination of the eye, and nasal passages, for in these the root of the difficulty will be frequently found. Cases of optic neuritis due to influenza alone, occur very rarely. They have been reported.

Nervous disorders of vision, weakness of accommodation, and twitching of the lids, are not uncommon in persons who have had a severe influenza and a protracted convalescence. Such troubles are not infrequently aggravated by the patient's efforts to read too soon after his acute symptoms have subsided, and especially by prolonged attempts to read in bed.

Ear affections due to influenza are much more common. Every epidemic of this disease brings to the aurist a large increase in the number of acute ear cases under his care, and these cases are of a type distinctly more virulent, as a rule, than similar infections due to other diseases in which the ears are attacked. Many of these cases develop mastoiditis, and rapid destruction of this bone is frequently found. It is safe to say that no other disase is so frequently responsible for severe ear infections in older persons as influenza.

The pronounced catarrh accompanying the disease is of course responsible for this fact; the accessory sinuses of the nose and the middle ear and Eustachian tube being lined with a continuation of the mucous membrane lining the nasal chambers proper, inflammation and swelling of the latter, if severe, means a similar state throughout. The aching pains in the head and ears so commonly complained of should not be explained as neuralgic, in the sense that this term is usually used; they are due to acute congestion and inflammation of regions that are under our control in the majority of cases.

It is a mistake to wait for the rupture of the tympanic membrane to relieve the distressing earache, for instance. This pain is nearly always due to pressure caused by accumulated fluid in the ear drum, and while this is sufficient in most cases to burst its way through the macerated drumhead in time, the infective matter has during this interval a pronounced tendency to seek the antrum and other cells of the mastoid bone. Many of these sufferers make the mistake of putting such mixtures as warmed sweet oil and laudanum into the ear to relieve the pain. This is wrong, because the laudanum does little more good than plain warm water put into the ear would do, and the sticky mess thus made in the ear is surgically unclean and favors the activity of the infective agents, once they have penetrated the drum membrane.

A more logical and effective plan is that of applying to the drumhead a gauze drain, whose inner half has been soaked in glycerine. This undoubtedly acts well in many cases if used early, having a tendency to abstract from the drum a portion of the fluid collected in it. Three or four grains of carbolic acid to the ounce of glycerine does no harm, and is believed to be of advantage not only for its antiseptic properties, but on the ground that it acts as a local anesthetic of some value. The glycerine drops should be warmed before using. Heat applied to the inflamed ear by means of a hot-water bag, or bags of salt, etc., is very comforting and helpful. If these measures do not bring relief within an hour or two, nothing but an opening of the drum membrane and release of the accumulated fluid will do so, and a free incision should be made in the membrane for this purpose. The term "paracentesis" should not be used in this connection—the stab wound indicated by it, and even yet sometimes depended on in practice, being of little or no value as a therapeutic measure. A free opening made in the drumhead relieves the pain, shortens the after-period of discharge, and preserves the hearing, since knife wounds heal more readily and cleanly than ruptures of the membrane—and, above all, greatly lessens the danger of extension of the disease to the mastoid bone.

A fairly large number of influenza patients have ear troubles of a less severe form than this: Dullness of hearing, a feeling of stuffiness in the head, and noises in the ear (tinnitus) are often complained of. These are cases of catarrh of the Eustachian tube, and are, as a rule, readily cleared up with inflations by the catheter, repeated at intervals of a day or two for a week or ten days, though some of them are very persistent even under the most painstaking treatment.

Another form of ear trouble common in influenza patients is the painful condition of the canal, due to furuncles. The pain of this trouble is often intense and cannot be distinguished from that due to middle ear inflammations. These cases are commonly made more tedious by the introduction of such messy oils as I have spoken of. Nothing but a free opening of these furuncles, they are nearly always multiple, will cut short the pain and deafness caused by them.

Children suffer from influenza more generally than is recognized. In them the systemic symptoms are not so much complained of as in adults, but the numerous cases of cold in the head associated with earaches and middle-ear abscess seen in children during these epidemics, undoubtedly owe their infection to the same germs that are affecting the older members of the family with grippe. Such cases are, of course, most common among children who have adenoid vegetations in the pharynx, and correct treatment of cases of this kind should always include a clean removal of the adenoid growths. Lacking this the ear troubles are almost certain to persist or to recur from time to time.

1076 Boston Road

The Nurse's Obstetric Knowledge.—In a recent book on midwifery for nurses some opinions are expressed by the reviewer which are not in sympathy with the author's statements. The latter thinks that a nurse might treat chorea in pregnancy. The reviewer regards this as extremely inadvisable. The author says that he thinks "a nurse ought not to perform version in England. If she intends to practise midwifery in some foreign country, where doctors are few and far between, she may obtain special instruction with the phantom and fetus, and learn how to turn, when to turn, and when not to turn. The doctrine that it is better for a patient to run the risk of dying of hemorrhage than to have version performed by a nurse sounds a hard one, but the ordinary training of a nurse does not develop sufficient manipulative skill for her to perform version with safety, and unless she were given much more training than is at present considered necessary she would be very likely to do her patient grievous bodily harm." With this, as applied to version in placenta prævia, or to version early in labor, the reviewer entirely agrees, but he thinks it may reasonably be said that if a nurse when called to a case finds the membranes unruptured, the os uteri fully dilated, the child lying transversely and freely movable, she does better if she takes hold of a foot and delivers than if she sends for a doctor and runs the risk that the membranes may rupture, the liquor amnii escape, and the uterus contract round the child before he comes. In such cases there is hardly any risk in version, the risk being to the child in extraction, and extraction in breech cases is recognized as part of a midwife's duty.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

New York, April 27, 1907.

INFANT MORTALITY IN LARGE CITIES.

THE death rate of infants in all the large cities of the civilized world is far greater than it should be. This excessive mortality is ascribed to a variety of causes. In New York the chief reasons that infants die prematurely are overcrowding in the tenement districts, injudicious feeding, the impossibility or rather the great difficulty of procuring unpolluted milk at a moderate price, and the fact that many women of the working class labor themselves, either at home or in factories, thereby neglecting their infants. However, the situation here, so far as infant mortality is concerned, is hardly so bad as in London. In the British metropolis the death rate among the young and the great increase of degeneracy are exciting much concern, and of late the matter has been discussed from all points of view and by all sorts and conditions of men.

The most lamentable feature as regards London, and it must be said to a lesser extent as regards all large British cities, is the ever-increasing habit of women drinking at the bars of saloons. This in itself must react disastrously upon the offspring. But the worst phase of the matter is that not only do women of the lower classes frequent saloons, they also take with them their infants in arms, to whom they give beer or strong spirits. The question has become recently a public scandal in London, and one of the most brilliant journalists of that city has been writing a series of graphic articles narrating all the facts of the case.

So great an impression has been caused by the publication of these articles that on March 4 a large conference was called to discuss the matter, at which were present eminent men of all professions, the medical profession being especially well represented. The chair was taken by Sir Thomas Barlow, and speeches were made by Sir Victor Horsley, Sir Lauder Brunton, and Professor Sims Woodhead. Sir Thomas Barlow pointed out that the birth rate of Great Britain was going down in every division of society, and at the same time, so far as the children of the town were concerned, infant mortality was not lessening. In his opinion the panacea for the evil lay in the improvement of education and in the teaching of hygiene and temperance in the schools. As to the immediate peril of women drinking in saloons and teaching infants to drink also, protection should be afforded the infants in some way. The problem was to devise legislation, short, simple, definite, and direct, to meet the peril.

Sir Lauder Brunton spoke to the same effect, saying that it must be quite evident that the custom of giving infants gin or gin and water was a process of slow poisoning which destroyed the child one would say body and mind, were it not that very often the body was destroyed before the mind had had time to develop. Other speakers urged the necessity of legislation to stop as quickly as possible the custom of women taking infants in arms to saloons and giving them strong drink, as the results must be disastrous in the extreme.

While New York does not suffer to any extent in its mortality rate from the custom of women drinking and teaching children to do the same, yet in one respect, as concerns the influence on the death rate, the conditions in New York and London are very similar. The state of the milk supply is referred to. In London this, according to all accounts, is much worse than in New York. The *Lancet* has had recently special articles treating of the way in which milk is retailed in small general provision shops. It appears that in London something like 80 per cent. of the shops in which milk is sold are of this character. The sanitary state of these shops leaves much to be desired, and indeed from all points of view the milk supply of London is susceptible of great improvement. However, the physicians of London and to a lesser extent the population generally seem to be awakening to a realization of this fact, and no doubt, as is the custom in Great Britain, reforms will be introduced slowly but surely. The British people are not quick to move, but when they do move they usually do things thoroughly.

THE RIGHT UPPER ABDOMINAL QUADRANT.

IT is not so many years ago that the interest of the medical profession was centered in the lower right abdominal quadrant. But now we find that the appendix and the right ovary, having been thoroughly exploited, must bow to the upward march of progress and retire in favor of that group of organs and structures situated in the corresponding upper quadrant of the abdomen. Here may be included the gall-bladder and its ducts, the pylorus and first part of the duodenum, the head of the pancreas, and the right kidney, which together offer to the surgeon many varied opportunities for differential diagnoses and operative procedures. Thus an attack of pain in the region referred to may be due to stones in the gall-bladder or the common duct, to cholecystitis, stricture of the pylorus, ulcers or perforations, pancreatitis, and a number of other conditions. The differential diagnosis of these various disturbances is surrounded by many difficulties, and only too often must the surgeon wait for an exploratory laparotomy to reveal the true state of affairs. The question is very ably discussed in a recent paper by F. B. Lund (*Boston Medical and Surgical Journal*, March 21, 1907), who refers to the upper abdomen as the borderland not only of surgery, but also of medicine. The surgeon by early operation in cases of gallstones and gastric ulcer has given us our present knowledge of the pathology of these diseases in their early and curable stages. This fact

is of great importance to the general practitioner of medicine, who may acquire a greater skill in the diagnosis of these conditions if he attend the operation itself rather than gain his knowledge from the autopsy table. There a diagnosis may be confirmed or disproved and on a subsequent occasion he will be in a position to profit by the combination of clinical observation and that of the operating table.

As the diagnosis of pathological conditions in the upper abdominal quadrants is so often in doubt, the surgeon must be prepared to deal with whatever lesions may present themselves. Thus, where a case is supposed to be one of cholecystitis, the operator must be ready to change his opinion as soon as the abdominal cavity is opened and to perform a gastro-enterostomy or other operative procedure in case there is present an ulcer of the duodenum or pylorus. The early surgery of these conditions has been proved by experience to be perfectly safe in competent hands, and it is only in the late or neglected cases that the mortality is high. It is only by stimulating the interest in this comparatively new field that we can hope for better results in the surgical treatment of lesions of this portion of the abdominal cavity, for such interest means that the possibility of these various lesions will be borne in mind when the physical signs and symptoms in any given case point to some trouble in this section.

THE PROPHYLAXIS OF MENINGITIS.

The question of the prevention of epidemic cerebro-spinal meningitis is a subject which is of the most vital interest to the whole civilized world and especially at the present time to the medical men of New York. Since the cessation of the actual epidemic, which was at its height in 1904 and 1905, cases have occurred endemically in numbers sufficient to keep the subject alarmingly before the minds of those most conscious of our comparatively helpless condition to prevent them.

The prevention of any infectious disease, of course, is directly dependent upon the detailed knowledge we may be able to gain as to the organism which causes it, its vitality, its favorite haunts, its most common roads of invasion. The diplococcus of Weichselbaum is now pretty well understood as to its biological functions, but there is still a great deal of work to be done. The difficulties of its cultivation, we believe, have generally been much overestimated. The German observers, especially, lay much stress upon its delicate reaction to temperatures and the necessity of great richness in the constitution of the media—while several observers here in America appear to have been able to cultivate the organism with much greater ease and have shown with sufficient certainty that the organism is unfortunately not as delicate as had been supposed. Its resistance to external environment when not kept upon artificial media—that is to say, just as the organism would be cast off by the infected patient—has been variously determined. Sunlight will kill the meningococcus, according to Bettencourt and Francas, in two hours; according to v. Lingelsheim, in six hours. Complete drying will kill it—certainly in the space of twenty-four hours.

These observations, added to the fact that, so far, it has not been possible to isolate definitely identified meningococci from dust, furniture, and other objects in the rooms of patients, seem to indicate rather strongly that few if any of the new cases are traceable to an infection.

The investigations into the nasal and pharyngeal secretions of individuals in direct contact with patients have yielded rather more significant results. During the meningitis epidemic in Silesia the diplococcus was found—often in pure culture—in the throats of many perfectly healthy people. Of those in contact with patients, as many as 75 per cent. were found to harbor the organism in their noses and throats, and this, not for a short period, but for weeks and months.

Kutscher, in a thoughtful article in the *Medizinische Klinik*, 1907, No. 12, concludes that it is in the infection by agency of these indirect carriers that we must look for most of the propagation of the disease, and that in these persons we have the factor at present most reasonably offering hope for successful prophylaxis.

The difficulties of formulating a practicable plan on the basis of such knowledge are, of course, tremendous, but at any rate until our knowledge becomes more complete there can be no question that isolation, with all the usual precautions, is at least advisable for these cases, including their exclusion from the general wards of hospitals and the utmost care of disinfection of nose and throat of those in contact with the patients before they mingle with other and possibly more susceptible individuals.

ACUTE SUPRARENAL INSUFFICIENCY.

This condition is believed by Sergent and Bernard to be responsible in many cases for sudden death where no other cause is apparent. Two functions may be associated with the suprarenal gland, one an antitoxic, the other an angiotonic. The former becomes active against the various toxic substances which are developed as the result of muscular exertion as well as those due to other endogenous sources. The angiotonic effect is manifested by the phenomenon of vasoconstriction. Among the conditions which lead to this type of glandular insufficiency are tuberculosis, hemorrhages, neoplasms and inflammatory processes, and the affection may run an acute, a subacute, or a chronic course. In the acute cases which run their course in a few days, the alarming symptoms come on very suddenly and death follows rapidly. There may be no other previous evidence of trouble, and the subjects are often apparently healthy young men. Otherwise the condition is marked by an attack of extremely severe pain in the lumbar region accompanied by anorexia, vomiting, diarrhea, headache, prostration, and a small and weak pulse, with a tendency to collapse. The general symptom complex would lead one to suspect acute poisoning, cholera, typhoid fever, or some acute abdominal condition. Sudden death from this affection of the suprarenals during apparently good health assumes, therefore, considerable importance from the forensic standpoint, for it might be assumed that certain direct causes, such as trauma, slight infections, inflammations of the appendix or the adnexa, pregnancy, malaria, or vari-

ous forms of poisoning, acted as predisposing factors in the production of a suprarenal insufficiency.

From these observations it is quite apparent that the pathology of the suprarenal glands is not exhausted by a knowledge of Addison's disease and that other affections of the glands may exist. The diagnosis under any circumstances is surrounded by many difficulties. In the more chronic cases the administration of suprarenal extract is advised, and when a suspicion of beginning renal insufficiency exists a prophylactic treatment is indicated. Bernard states that this should consist of avoiding overexertion, traumata, infections, and intoxications, as well as the administration of tonics.

The Use of the Opsonic Index in the Diagnosis of Tuberculosis.

A further contribution to this subject was recently made by Drs. I. S. Stewart and L. C. Ritchie in a paper presented to the Edinburgh Medico-Chirurgical Society (*Lancet,* March 23). The method which they submitted and at which they had been working for some time was one which rendered possible a diagnosis of tuberculosis even when the signs and symptoms were not conclusive. It consisted in the injection of a minute dose of tuberculin R. in conjunction with the observation of the tuberculoopsonic index of the blood before and after inoculation. The conclusions were based on observations made on 122 consecutive cases of medical and surgical tuberculosis. The cases were divided as follows: 1. Those in which there was reasonable ground for diagnosing tuberculosis. In many diagnosis was based on pathological proof (examination of discharges, operation, etc.), and in the remainder by continued clinical observation. 2. Either normal cases or those suffering from diseases other than tuberculosis. The authors drew attention to the fact that several observers had shown that the tuberculoopsonic index varied slightly in health. The normal limits of variation were from 0.8 to 1.2. The first group (tuberculosis) consisted of 82 cases. The indices of 41 fell within the normal limits and 41 outside. In the second group there were 40 nontuberculous cases, of which 29 were within and 11 outside the normal limits. A diagnosis based on one examination of the tuberculoopsonic index would have resulted in an error of diagnosis in one-half the number. In the nontuberculous cases 27.5 per cent. were outside the normal limits, and a reliance on this test would have led to error to this extent. In acute tuberculous cases the swinging index might also lead to error in diagnosis. In a paper in conjunction with Dr. D. Lawson of Banchory it had been shown that if a small quantity of tuberculin R. were injected into a tuberculous patient there was a diminution in the index, but the reverse occurred in a healthy case. The conclusions were: (1) the opsonic index *per se* was an unsatisfactory means of diagnosis, as both tuberculous and nontuberculous cases fell within and without normal limits; (2) if a negative phase appeared after inoculation the existence of tuberculosis might be diagnosed; and (3) the absence of a negative phase indicated the absence of a tuberculous infection.

The Mimicry of Malignant Diseases.

It is very often a most difficult matter to differentiate between malignant and benign growths, for the clinical features and macroscopical appearances of both may closely agree, and it is only by the microscopical examination that the difference can be detected. In this connection it may also be assumed that in many instances a "cure" can be traced to the fact that the offending tumor removed by operation was not really of a malignant character. In the large intestine particularly a neoplasm may closely simulate malignant disease, not only in its general appearance, but also in the symptoms which it causes, and tuberculous lesions of the cecum or the ascending colon may produce effects which can only with difficulty be distinguished from those of cancer. Moynihan, writing in the *Edinburgh Medical Journal* for March, 1907, states that he has twice performed colectomy for supposed carcinoma, when subsequent examination of the tumor showed its undoubted tuberculous nature. Aside from these cases, which are very uncommon, there are certain tumors of the large intestine and the sigmoid flexure which present all the characteristic signs and symptoms of malignant disease, yet prove to be nothing more than simple inflammatory conditions. Moynihan gives the detailed histories of six cases in which this error was made, and although they differ in many respects, they all present a close resemblance if not an actual identity of symptoms with those of malignant disease. It would appear that the inflammatory tumors of the large intestine are perhaps more frequent than we have supposed. The pathological features are not always the same. The inflammation may begin in and penetrate the mucosa, a false diverticulum may form and may perforate, extensive undermining ulcerative processes may be combined with a form of polypoid growth, and finally the inflammatory deposit may affect the peritoneal coat chiefly or solely, leaving the mucosa supple or intact.

The Pathology of Burns.

As considerable doubt still exists regarding the cause of death in fatal burns, all investigations on the subject, particularly if they are of an experimental nature, will prove of general interest. Among the most recent of these is one by Pfeiffer (*Virchow's Archiv,* Vol. 180, No. 3), which was carried out on a large number of rabbits. He claims that death from burns in typical cases is caused by a toxin which circulates in the blood and is excreted by the kidneys unchanged. It is probably a disintegration product due to the action of heat on the albumin molecules. Other investigators have claimed that this toxin exerts a hemolytic or agglutinating effect, but this Pfeiffer denies. He thinks, moreover, that if death results within a period of about three hours, it is due to the nervous shock rather than to any toxic action. This may also exert an influence at a later period, from two to three weeks, by weakening the organism in such a manner that it readily succumbs to a secondary infection. Weidenfels and von Zumbusch (*Archiv für Dermatologie und Syphilis,* Vol. 76), working independently, come to a similar conclusion, believing that the toxic material is absorbed directly from the burned skin. These observers also made some experiments to determine a suitable method of treatment, and found that excellent results attended the subcutaneous infusion of decinormal salt solution even when one-third of the entire skin area was involved. Cardiac stimulants are immediately indicated, including caffeine or coffee, alcohol, camphor, and strophanthus or digitalis. Heart depressants

such as morphine should be avoided. The infusions may be preferably given under the healthy skin in several places at once in order to save time and obtain an immediate effect. As the results with the infusion treatment have been so uniformly good, the procedure, which is simple and easily applied, commends itself to further trial.

Domestic Animals in the Etiology of Infectious Diseases.

The rôle which the ordinary household pets may play in the dissemination of a considerable number of infectious diseases is not sufficiently appreciated by the laity. Attention has often been called to the danger which attends the more or less intimate contact between such animals and the members of a household, and yet the warning is little heeded. Among children particularly the fondness for certain pets is not limited to such association during the daytime, but must be satisfied by taking the animal to bed. Letourneur, in an interesting article in the *Bulletin général de Thérapeutique*, October 23, 1906, calls attention to the large number of infectious conditions prevalent among domestic animals which can be readily transmitted to human beings. Prominent among these is a series of parasitic skin diseases of dogs and cats which are very difficult to get rid of in the human patient, especially if the original source of the infection is not eliminated. The *Tænia echinococcus* also spends part of its life cycle in the intestinal canal of the dog, and it is most often found in persons who come into frequent contact with these animals. Investigation has shown that cats are also apt to contain this parasite, and so the danger of infection is correspondingly increased. There is moreover a form of diphtheria found in birds which is readily communicated to the human subject, and parrots are often afflicted with a type of infectious enteritis which has likewise been demonstrated in persons who had come into contact with these animals. It has also been frequently shown that tuberculosis may be communicated from man to dogs, cats, and birds, and although it has never been definitely proved that the reverse can take place, the possibility of such an occurrence must not be lost sight of. If in conclusion we remember the readiness with which rabies may be communicated from cats and dogs to human beings, it is quite evident that if we desire to keep such animals about us and live in more or less immediate contact with them, a most careful watch must be kept over their health and general condition.

Syphilis and Tabes.

The belief that tabes is directly dependent upon syphilitic disease has gained such widespread recognition that those who oppose the idea find it necessary to carry their studies in the most varied directions in order to substantiate their contentions. A French surgeon, Dr. Peyronie (*Centralblatt für Nervenheilkunde und Psychiatrie*, No. 229, Vol. XXX.), who has had considerable experience with syphilis among the Arabs of Northern Africa, states that among many Mohammedans the disease is looked upon as a holy visitation, and that the possession of a syphilitic necrosis of the nasal bones is regarded as an honor. The disease has, therefore, become widespread, and it has come to be a rule among physicians practising in these countries that in treating an Arab it may be safely assumed that he has had syphilis. One writer is referred to who found that among 4,000 Arabs who consulted him in a professional capacity only 100 were free from acute or hereditary syphilis. It is a well-known fact, however, that among these people, tabes and other paralytic affections are comparatively rare or entirely unknown, and this fact is brought forward by Peyronie in opposition to the theory of these diseases with which the names of Erb and Fournier are so closely identified. The direct dependence of tabes on syphilis has not as yet been satisfactorily demonstrated, although it has been very widely accepted as a fact.

News of the Week.

Insanity in Murder Trials.—Senator Agnew has introduced in the State Senate a bill adding a new section to the criminal code relating to the insanity of a defendant indicted for a felony. It is provided that either the defendant's attorneys or the District Attorney may apply to any justice of the court in which the indictment is pending, for an order committing the defendant to a State hospital for the insane for observation. The motion must be based upon affidavits, executed by two duly qualified examiners in lunacy, which must show that a personal examination within ten days before the notice of motion satisfied the examiners that the defendant was insane. If the judge be satisfied that the interests of justice so require, he shall make an order committing the defendant to a State hospital for the insane for observation for a period of not less than three, nor more than six, weeks. The Superintendent of the hospital or the physician in charge of the defendant shall report to the court at the end of three weeks the results of the observation, and should the defendant be detained in the hospital for more than three weeks a second report shall be made when he is returned from the hospital. Another bill introduced by Assemblyman Duell provides that in any criminal action wherein the issue of insanity is involved no evidence of statements made to the person alleged to be or to have been insane by a third party shall be introduced as showing or tending to show such insanity, or as aggravating such insanity unless the facts alleged to have been narrated be first proved.

Another Fire at McGill.—Less than two weeks after the disastrous fire which wiped out the MacDonald engineering building of McGill University, the Medical Building was also completely destroyed by fire on April 16. In addition to the usual equipment of a medical school the building contained one of the best medical museums in the country. The financial loss is placed at $500,000, though of course much of the material destroyed was practically priceless. It is supposed that the fire was of incendiary origin.

For a Federal Health Board.—The committee of one hundred appointed last June by the American Association for the Advancement of Science to further the project of founding a Federal Department of Health, held a meeting in this city on April 19. These Vice-Presidents were elected after Prof. Fisher had been elected President of the larger committee: President Eliot of Harvard, Felix Adler, Dr. William H. Welch, Dr. Lyman Abbott, President Angell of the University of Michigan, Jane Addams, Andrew Carnegie, Archbishop Ireland, Judge Lindsay of the Juvenile Court of Denver, and John D. Long, ex-Secretary of the Navy.

German Hospital and Dispensary Prizes.—On the occasion of the fiftieth anniversary of the German Dispensary Dr. Charles H. Jaeger announced the foundation of three yearly prizes to be known as the Marie Jaeger Memorial Prizes. The prizes are to be awarded for medical essays and consist of a first prize of $100, a second prize of $75, and a third prize of $50. The competition is to be open to members and collaborators of the German Dispensary and to members of the house staff of the hospital. The prizes are to be awarded on December 31 of each year. The essays are to be based on cases occurring in the service of the hospital and dispensary, and preference will be given to those embodying original thought or work. The right is reserved to withhold any or all prizes if the quality of the essays submitted is not sufficiently high or the numbers not sufficiently large. A committee is to be appointed to pass on the essays.

Plan for Hospital for Tuberculosis in Chicago.—A plan to establish in Chicago or its environs a free hospital for the treatment of tuberculosis patients is being considered. Dr. Wm. A. Evans, the new Commissioner of Health, will be one of the principal promoters of the project. It has been the object of a number of Chicago physicians to have a tuberculosis hospital, supported by the city, and Dr. Evans is ambitious to give this city an institution for the proper treatment of this disease.

In Honor of Lord Lister's eightieth birthday the *Münchener medizinische Wochenschrift* in its issue of April 2 prints a translation into German of Lister's classical series of articles containing the rudiments of the antiseptic theory as applied to the treatment of wounds, which began to appear in the *Lancet* of March 16, 1867.

Objection to Staten Island Tuberculosis Hospital.—The representatives of certain taxpayers have appeared before the Supreme Court at Richmond, Staten Island, and asked to have made permanent a temporary injunction obtained in December restraining Comptroller Metz and Charities Commissioner Hebberd from building a tuberculosis hospital on Staten Island. The Board of Estimate and Apportionment passed a resolution in favor of such an institution on the island, and it was approved by the Board of Aldermen. It is proposed to put up the building at Four Corners, near West Brighton, at a cost of about $50,000.

The Tuberculosis Question in Richmond.—The City of Richmond, Va., in response to an appeal from its health officer for funds to be used in fighting tuberculosis, decided to dispense with summer music in the parks, and turned over to the health department the sum of $2,800 usually expended for the former purpose.

The American Mosquito Extermination Society held its fourth annual meeting in this city last week, and Dr. O. L. Howard of Washington and Dr. E. Porter Felt, the New York State Entomologist, among others, described what had already been done in the way of checking the multiplication of the mosquitos in certain parts of this and other countries. It was shown that the complete extermination of the insects was simply one of funds and an enlightened public spirit.

A Heraldic Recompense.—An uncommon honor has been granted by King Edward to Sir Frederick Treves and Sir Francis Laking in recognition of their services during his attack of appendicitis in 1902. The King by royal warrant has granted them "honorable augmentation" to their arms, consisting in the addition to their shields of one of the lions from the royal arms. James I.'s apothecary, Gideon Delaune, received a similar reward for services rendered to his sovereign.

A Society of Eternal Youth.—The newspapers state that a society which already has several hundred members has been formed in Iowa for the purpose of prolonging life and preventing illness. All members upon joining must sign a pledge that they will continually assert that it is nothing but custom and habit of thought that causes people to be sick, grow old, or die. Any member who is reported sick from any disease, and is confined to his bed for a continuous period of three days is to be fined for the first offence, for the second offence he is to be suspended from membership, and for the third offence expulsion from the society is the penalty.

Legislation Against Tobacco.—The State Assembly of Wisconsin has adopted a bill prohibiting the sale of tobacco in any form to persons under sixteen years of age. The bill also prohibits such minors from using tobacco. The Illinois House has passed a bill prohibiting the selling of cigarettes or cigarette papers in that State.

Smoke Nuisance Award.—The Court of Appeals has just affirmed a verdict for $4,000 damages recovered by a plaintiff against a large corporation for damages arising out of the defendant's violation of the smoke nuisance law.

New Property for Lincoln Hospital.—The entire block bounded by 141st street, 142d street, the Southern Boulevard, and Wales avenue has been bought for a sum said to be in the neighborhood of $100,000, by the trustees of the Lincoln Hospital. The property is to be given to the institution, Morris K. Jesup and Miss Emily Booth being the principal donors. The Lincoln Hospital was established where it now stands, on the block bounded by 141st and 142d streets, Concord avenue, and the Southern Boulevard, about ten years ago. The increasing population of the Bronx has overtaxed the present building, and it is proposed to build additional wards on the property just bought. A convalescent ward will also be established.

Ambulance Accident.—While a Roosevelt Hospital ambulance was conveying a woman ill with pneumonia and her ten months baby to Bellevue Hospital last Sunday, the ambulance was run into by a crosstown car at the intersection of Thirty-fourth street and Broadway. The ambulance was badly smashed and the patients were severely jolted about, but through the surgeon's quickness of action were kept from serious injury. They finished their trip to the hospital in a New York Hospital ambulance.

Coney Island Hospital Opened.—The formal opening of the Coney Island Reception Hospital was held last week in the presence of a number of city officials. The hospital was started in 1901 for emergency cases, and has been kept open only during the summer months. It will now be operated the year around until the completion of a new and larger structure, now contemplated, which will be located in Surf avenue, near Fifth street. The hospital has eight beds and additional accommodations for emergency demands.

The Pathological Society of Philadelphia, which is one of the oldest, if not the oldest society, of its kind on this continent, will celebrate its semicentennial in May, 1907. The celebration will extend over two days, Friday, May 10, and Saturday,

May 11. On the first day addresses will be delivered by Dr. Frederick G. Novy of Ann Arbor, Michigan, on "The Rôle of Protozoa in Pathology"; by Dr. Simon Flexner, of the Rockefeller Institute, New York, on "The Newer Pathology"; and by Dr. A. E. Taylor, of the University of California, on "The Dynamic Point of View in Pathology." In the afternoon, at four o'clock, a commemorative meeting will be held in the Pennsylvania Hospital, where the first meetings of the society, in 1857, took place. At this meeting, Dr. William Osler, Regius Professor of Medicine, Oxford University, will deliver an address on "Pathology and Practice." At a dinner in the evening prominent men from all parts of the country will respond to toasts. An exhibition meeting of interest to pathologists, clinicians, and surgeons will be held on Saturday, May 11.

Plague in India.—According to despatches from Simla there were 75,000 deaths from the plague in India during the week ended April 13. Seventy thousand of these occurred in Bengal, the United Provinces, and the Punjab. Since the disease began in the Punjab in October, 1897, nearly 1,500,000 deaths have occurred.

Professor Politzer's Retirement.—At the end of the summer term of 1907 Hofrat Professor A. Politzer will have arrived at the age limit beyond which, according to the laws of Austria, he may not retain his chair at the University of Vienna, and will, therefore, resign his position, as well as the directorship of the Vienna Ear Clinic. At the same time the lectures which he has delivered throughout forty-six years will cease to be given. A committee has accordingly been formed for the purpose of organizing a suitable testimonial of the world-wide esteem in which this master of otology is held, to be presented on the occasion of his relinquishing the chair he has occupied so long. It was originally intended to hold a formal public celebration to which representatives of the world's otological societies should be invited, but Professor Politzer on becoming aware of these preparations requested that owing to several recent deaths in his immediate family no public demonstration take place. It has been decided, therefore, to issue a medal bearing a portrait of the master. A copy of this in gold is to be presented to Prof. Politzer on the designated day; other copies, some in silver and some in bronze, will also be struck off to serve as souvenirs of the eminent scientist. These will be put at the disposition of those who wish to subscribe to the celebration. Together with the medal an address, containing the names of all the subscribers, will be presented to Prof. Politzer. All communications should have plainly written the names, titles, and the exact address of the sender and should be accompanied by a remittance of $5 for the silver or $2.50 for the bronze medal and be sent to the treasurer, Dr. D. Kaufmann, Vienna, VI., Mariahilferstrasse 37. Any surplus that there may be, after the necessary expenses have been met, will be put at Prof. Politzer's disposal as a fund to further some scientific object. Subscriptions must be in the hands of the treasurer before May 15, 1907.

Appointment of Dr. Evans.—Dr. Wm. A. Evans has been appointed Health Commissioner of the City of Chicago by Mayor Busse.

Jefferson Medical College.—Dr. John H. Gibbon has been elected professor of surgery and of clinical surgery in succession to Dr. John H. Brinton, deceased.

Association of American Medical Colleges.—The next meeting of this association will be held in Washington, at the Hotel Raleigh, Monday, May 6, beginning at 10 A.M. The program will consist of two parts, one of which is educational and open to visitors. The second part of the program relates to the business of the association, and will be taken up in executive session at the conclusion of the first part. The president is Dr. George M. Kober of Washington and the secretary is Dr. Fred. C. Zapffe, 1764 Lexington street, Chicago.

Association of American Physicians.—The twenty-second annual meeting of the Association of American Physicians will be held in Washington on May 7, 8, and 9, 1907, under the presidency of Dr. Francis P. Kinnicutt. An amendment to the constitution and by-laws will come up for action, providing that not more than thirty papers shall be presented at any meeting of the association, these to be selected by the Council from among the titles handed in by March 1 of the year in which the meeting occurs. On May 7 there is to be a reception by President Roosevelt at the White House to members of the association and ladies accompanying them. The secretary is Dr. Henry Hun, 149 Washington avenue, Albany.

American Gastro-Enterological Association.—The tenth annual meeting of this organization will be held in Atlantic City, June 3 and 4, 1907, under the presidency of Dr. H. W. Bettman of Cincinnati. The secretary is Dr. Chas. D. Aaron of Detroit.

National Association for the Study and Prevention of Tuberculosis.—The third annual meeting of this association is to be held in Washington May 6 to 8, 1907. The preliminary program provides for a very active series of sessions, and in addition to the general meeting there will be five sections as follows: Sociological section, clinical and climatological section, pathological and bacteriological section, section of tuberculosis in children, and surgical section. The meeting will be held under the presidency of Dr. Hermann M. Biggs. The secretary is Dr. Henry Barton Jacobs of Baltimore, and the executive secretary is Dr. Livingston Farrand of this city. The chairman of the local committee of arrangements is Dr. George M. Kober of Washington. President Roosevelt will receive the members of the association, ladies, guests, and visitors at the White House on the afternoon of May 7.

American Academy of Medicine.—At the annual meeting of this organization to be held in Atlantic City June 1 to 3, 1907, the president, Dr. Casey A. Wood of Chicago, will take as the subject of his address "The Medical Career and the Intellectual Life." One symposium will be devoted to considering the relation of the medical profession to the housing of the people, and another to the relation of the medical profession to legislation.

Mississippi State Medical Association.—At the meeting of this organization held in Gulfport on April 12 officers were elected as follows: *President*, Dr. R. S. Curry, Columbus; *Vice-Presidents*, Dr. H. R. Shanck, Jackson; Dr. T. F. Elkin, Tupelo; Dr. R. D. Sessions, Natchez; *Secretary*, Dr. E. F. Howard, Vicksburg; *State Board of Health*, Dr. L. D. Dickerson, McComb City; Dr. G. S. Bryan, Amory; Dr. E. A. Cheek, Arcala; Dr. John Darrington, Yazoo City; Dr. D. J. Williams, Ellisville. The next meeting will be held in Natchez in April, 1908.

Central Oklahoma Medical Association.—At

the annual meeting of this organization, held in Guthrie on April 10, officers as follows were elected for the ensuing year: *President*, Dr. H. Coulter Todd, Oklahoma City; *First Vice-President*, Dr. J. H. Barnes, Helena; *Second Vice-President*, Dr. N. Rector, Henessey; *Secretary* and *Treasurer*, Dr. Geo. A. Boyle, Enid.

Otoe County (Neb.) Medical Association.—At its annual meeting, held in Nebraska City on April 6, this society elected the following as officers: *President*, Dr. Claude Watson; *Vice-President*, Dr. M. M. MacVean-Edmonds; *Secretary* and *Treasurer*, Dr. C. P. Crudup.

Washington County (Ill.) Medical Society.—At the annual meeting, held in Nashville on April 12, this society elected the following officers: *President*, Dr. W. D. Carter of Nashville; *Vice-President*, Dr. H. W. Wolf of DuBois; *Treasurer*, Dr. S. P. Schroeder of Nashville; *Secretary*, Dr. D. S. Neer of Beaucoup.

Hampden (Mass.) Medical Society.—At the annual meeting held in Springfield on April 16 officers for this society were elected as follows: *President*, Dr. C. A. Allen of Holyoke; *Vice-President*, Dr. George S. Woods of Springfield; *Secretary* and *Treasurer*, Dr. T. S. Bacon of Springfield.

Fairfield County (Conn.) Medical Society.—Officers as follows were elected at the one hundred and fifteenth annual meeting of this society, held in Bridgeport on April 9: *President*, Dr. Edwards M. Smith of Bridgeport; *Vice-President*, Dr. David C. Brown of Danbury; *Treasurer*, Dr. J. D. Gold of Bridgeport; *Secretary*, Dr. Frank W. Stevens of Bridgeport.

Henry County (Ia.) Medical Society.—The annual election of officers for this society, held at the meeting in Mt. Pleasant on April 9, resulted as follows: *President*, Dr. F. T. Stevens of Mt. Pleasant; *Vice-President*, Dr. Pittman of Salem; *Secretary* and *Treasurer*, Dr. J. N. Day of Mt. Pleasant.

German Medical Congress.—The seventy-ninth Congress of German Men of Science and Physicians will be held at Dresden this year from September 15 to 21.

Golden Belt (Kan.) Medical Society.—At the meeting of this organization held in Abilene on April 4, officers were elected as follows: *President*, Dr. Howard N. Moses of Salina; *Secretary*, Dr. William S. Yates of Junction City; *Treasurer*, Dr. John D. Riddell of Enterprise.

Middlesex County (Conn.) Medical Society.—The following officers were elected at the one hundred and fifteenth annual meeting of this society, held in Middletown: *President*, Dr. Charles B. Young of Middletown; *Vice-President*, Dr. James Murphy; *Clerk*, Dr. John E. Loveland; *Censors*, Dr. John E. Bailey, Dr. C. H. Hubbard, and Dr. M. C. Hazen; *County Reporter*, Dr. John H. Mountain.

Massachusetts Homeopathic Society.—At the sixty-seventh annual meeting of this society, held in Boston on April 10, officers were elected as follows: *President*, Dr. John P. Rand, Worcester; *Vice-Presidents*, Dr. Fred W. Halsey, Boston, and Dr. Nathaniel R. Perkins, Dorchester; *Corresponding Secretary*, Dr. Charles T. Howard, Boston; *Recording Secretary*, Dr. Thomas E. Chandler, Boston; *Treasurer*, Dr. Thomas M. Strong, Boston. It was decided to hold the next meeting in Worcester.

Cass County (Ill.) Medical Association.—At the annual meeting of this society held in Virginia on April 12 officers for the coming year were elected as follows: *President*, Dr. C. E. Soule, Beardstown; *Vice-President*, Dr. J. W. Houston, Virginia; *Secretary*, Dr. J. A. McGee, Virginia; *Treasurer*, Dr. C. M. Hubbard, Virginia.

The Late Dr. George B. Fowler.—At a meeting of the Medical Association of the Greater City of New York, held April 15, 1907, the following report was presented and adopted. *Whereas*, It has pleased the Almighty to call from his earthly labors George Bingham Fowler; *Resolved*, That the following minute be entered upon the records of the Medical Association of the Greater City of New York: Dr. Fowler was born in Alabama in 1847 and died in the Borough of Manhattan, New York City, on March 6, 1907. He was graduated from the College of Physicians and Surgeons, New York, in 1871. He served as assistant in the Department of Physiology in that school under the late Professor John C. Dalton, and for many years, in one or another capacity, he was connected with the Metropolitan Board of Health. He was associate editor of the *American Journal of Obstetrics*, contributing many articles on the diseases of children. Under Mayor Strong he was Commissioner of Health of the City of New York. He served for years as Attending Physician to the New York Infant Asylum and the Bellevue Hospital. In the latter hospital he was instrumental in founding the Training School for Male Nurses. He was Professor of Clinical Medicine in the New York Polyclinic, and later at the Post-Graduate Medical School, and he was an active member of many of the local and national societies. He was twice elected president of the Medical Society of the County of New York. Amidst all these activities his genial temperament prevailed to form warm friendships and deep loyalty on the part of a wide circle of patients. He carried sunshine into the sick-room and imparted courage to the ailing. Here his presence was indeed a benediction. In civil life he set an example of fidelity to duty which might well be emulated by others. (Signed) Egbert H. Grandin, William H. Porter, Leonard Weber, Committee.

Obituary Notes.—Dr. R. F. Michell of Montgomery, Ala., died on April 19 at the age of eighty years. He was born in Charleston, S. C., and served as surgeon in the Confederate army. He was the author of several books on medical subjects.

Dr. William M. Taylor of Talladega, Ala., died on April 7 at the age of eighty-one years. Dr. Taylor was a native of Sumner County, Tenn., but in 1839 his parents removed to Talladega and he continued to reside there for the rest of his life. He served as surgeon in the Seventh Alabama regiment, and as chief surgeon of Wilcox's brigade. Dr. Taylor was largely instrumental in the foundation of the Mobile Medical College, and was one of the incorporators of the Alabama School for the Deaf. He was a member of the Alabama legislature in 1876 and 1880.

Dr. W. Frank Morrison of Providence, R. I., died suddenly on April 9, at the age of forty-nine years. He was born in Millville, Mass., and was graduated from Harvard Medical School in the class of 1882. Shortly afterward he began practice in Providence, where he had resided ever since.

Dr. George F. Gale of Brattleboro, Vt., died on April 14 at the age of seventy-nine years. He was born in Petersham, Mass., and was graduated from the Berkshire Medical College in Pittsfield, Mass.,

in 1855. He practised for a time in Cummington and Deerfield, and for a year was in charge of a smallpox hospital in San Francisco. He was surgeon of the Eighth Vermont regiment in 1861 and 1862.

Dr. William R. Campbell of Niagara Falls died on April 9 after a lingering illness. He was born in New York City in 1854 and received his medical degree from Buffalo University in 1880. Immediately afterward he began to practise in Niagara Falls. Dr. Campbell was a curator of Buffalo University and president of its alumni association; he was also president of the Niagara Falls Academy of Medicine, and was a surgeon in the New York State National Guard.

Dr. Stanley A. De Paul of Carlton, Mich., died on April 7 at the age of forty-eight years. He was a graduate of the Detroit College of Medicine, and practised in Carlton for over twenty years.

Dr. J. S. Korn of Texarkana, Ark., died suddenly on April 4 at the age of fifty years. He was president of the Howard County Medical Society, and had practised for many years in Southwestern Arkansas.

Dr. J. C. Kilgore of Monmouth, Ill., died on April 9 of septicemia, resulting from an infection contracted while performing an autopsy. He was born in Holmes County, Ohio, in 1840, and served three years in the Civil War in the Sixteenth Ohio Infantry. He was graduated from Rush Medical College in Chicago in 1869.

Dr. Isaac Lechtman of St. Joseph, Mo., died on April 11 at an advanced age. He was born in Russia and received his degree from the military medical school at St. Petersburg. After serving for some time as army surgeon, in 1871 he came to this country and settled in St. Joseph. He was president of the Missouri Medical Society in 1803.

Dr. E. A. Woodward of Madison, Wis., died on April 8 of grip, at the age of ninety years. He was born in Litchfield, Conn., and received his degree from the Berkshire Medical College in 1842. He practised in Connecticut until 1855, in which year he removed to Madison. He served as surgeon in the Civil War.

Dr. James D. Pendleton of Bedford City, Va., died on April 10 at the age of eighty-seven years. He was the son of Dr. Micajah Pendleton, who practised for fifty years in Buchanan, Va.

Dr. William W. Genge of St. Johnsbury, Vt., died on April 10 of pneumonia at the age of thirty-nine years. He was born in Canada, and in 1891 began practice in Hyde Park. Three years ago he removed to St. Johnsbury.

Dr. W. H. Jopes of Greenfield, Mo., died on April 9 at the age of seventy-three years. He was born in Gallatin, Tenn., and had practised in Greenfield since 1855.

Dr. Austin S. Tinsley of Augusta, Ga., died on April 16 after an illness of two weeks.

Dr. Alfred J. Yost, Mayor of Allentown, Pa., died on April 16 of pulmonary tuberculosis, at the age of thirty-seven years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1803. In 1805 he was elected Coroner of Lehigh County, and he was re-elected in 1893. He was elected Mayor of Allentown in 1905.

Dr. Wm. M. Kern died at Philadelphia on April 17, at the age of eighty-seven years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1847.

Obituary.

THOMAS HENRY WAKLEY, F.R.C.S.,

LONDON.

With Thos. H. Wakley, who died on April 5, passes away the second generation of editors of the *Lancet* in the same family, for he was the eldest son of the founder of this important medical journal. On the death of his father in 1862 the two sons came into the possession of the *Lancet*. The younger son, James, took the more active part in the conduct of the journal, devoting himself entirely to it, but Thomas contributed as joint editor though he kept on his surgical practice for some years. His brother James died in 1886 and from that time Thomas became senior editor. His son, who has been for several years joint editor, survives him, so the third generation of Wakleys continues to control the *Lancet*. The late Thomas H. Wakley was an alumnus of University College and also studied in Paris. He took his M.R.C.S. in 1845 and the fellowship four years later, having been elected assistant surgeon to the Royal Free Hospital, which he continued to serve as surgeon and consulting surgeon and as lecturer on surgery. He took much interest in anesthesia and contributed to his paper a record of one hundred experiments on animals with chloroform and ether, and other surgical papers during the fifties. A still earlier contribution was on the "entire removal of the os calcis and astragalus with the malleolar processes of the tibia and fibula." The urethral dilator which he designed while in practice will be known to specialists in that department. He contributed to Cooper's Surgical Dictionary, but practically all his writing was in the *Lancet*. The Hospital Sunday Fund owed much to the unwavering support of the two brothers, who were largely concerned in founding it. More recently Mr. Wakley and his son, as joint proprietors, founded the Lancet Relief Fund to help medical men overtaken by acute distress, the whole of the money being provided by them. Other agencies for the benefit of the profession always enlisted the sympathy and help of Mr. Wakley.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

LISTER'S BIRTHDAY—TUBERCULOSIS—PYORRHŒA ALVEOLARIS—GIANT GROWTH OF FEET—ENLARGED CLAVICLE AND JAW—OSTEOARTHROPATHY—OPERATIONS IN ASCITES—TEMPERATURE CHANGES—HYGIENE OF CHILDHOOD—OBITUARY.

London, April 5, 1907.

This is Lord Lister's eightieth birthday. As you are keeping it as well as we and the rest of the civilized world, I will confine my notice of the event to reporting that the arrangements made for its celebration here have been duly carried out. Yesterday the meeting convened by the Lister Institute was held at the Royal College of Surgeons, the president, Mr. Morris, occupying the chair. It was indeed a notable gathering, representing medicine and surgery, scientific and practical. As was intended members of the editorial committee were appointed, the republication of all Lord Lister's writings being the principal part of the celebration. A deputation was also appointed to wait upon Lord Lister to-day with the best wishes of the meeting. This, too, has been done, and we are all pleased to think that the venerable surgeon has expressed himself as gratified with the manner in which the esteem of his profession has been shown.

The appendix to the second interim report of the Tuberculosis Commission contains the comparative histological and bacteriological investigations made for the commission by Dr. Eastwood. The morbid processes set up experimentally by *Bacilli tuberculosis* of bovine and hu-

man origin and their cultural characters are compared. The general result is to emphasize the underlying unity of the morbid processes with every variety of *Bacilli tuberculosis*. Differences in severity were noted, due in part to the dose and virulence of the bacilli used and partly to the vary susceptibility of the animals inoculated. But even when animals of high resistance, as calves, are inoculated with bacilli of low virulence, lesions are produced in situations remote from the point of inoculation, such as those in bovines by bacilli of high virulence when the experimental conditions favor resistance. In highly susceptible animals, as monkeys and anthropoid apes, lesions are caused not only more chronic, but more acute by these less virulent bacilli. These and other considerations show the underlying unity of the morbid processes induced and the general resemblance in the characters of their growths on artificial media. But though Dr. Eastwood insists on the stability of the growth as a rule, he says at the same time there is interesting and very important evidence that the cultural and pathogenic characters of some of the viruses are not absolutely fixed. Instances were recorded of both diminution and increase of virulence, also of cultural luxuriance. These examples illustrate the variability and capacity for modification of the *Bacillus tuberculosis*, and from the evidence of the pathogenic and cultural instability Dr. Eastwood finds reason for assuming that during the course of a long residence in the human body a bacillus, originally of bovine origin, might undergo a modification of some of the characteristics which are met with in bacilli freshly isolated from the bovine, and that owing to this modification it might be indistinguishable from bacilli derived from cares of human disease.

The College of Surgeons did an excellent thing in appointing a dental surgeon to one of the lectureships, and no better selection could have been made than that of Mr. Kenneth Goadby. The result was a most suggestive contribution to our knowledge of a very troublesome affection which will interest every observant practitioner. Mr. Goadby is one of the foremost scientific dental surgeons, has devoted long years to bacteriological investigations in his specialty, and wisely based his lecture on these researches, taking for his subject pyorrhœa alveolaris. From careful examination of ninety cases, besides others of ulcerative stomatitis and allied conditions, he showed that a great many varieties of organisms are to be found, though there is not one so constant in pyorrhœa alveolaris as to appear as its cause. In fact, the bacteria found in these cases closely resemble those met with in gingivitis and ulcerative stomatitis. He described the bacteriological finds in thirty-six cases accompanied by general symptoms. In some he isolated a bacillus, which had the power of fermenting lactose, and referred to the observation of McConkey, who traced such an organism to a fecal origin. It may be that these bacteria are concerned in the production of the disease, but other organisms, including both varieties of staphylococci, are often found in milk. The suggestion, therefore, that contaminated milk may carry infective organisms along the alveolar margin and give rise to the general symptoms observed deserves consideration, or at any rate further investigation, especially as pyorrhœa alveolaris not seldom follows infectious diseases during which a milk diet has been employed. Mr. Goadby has successfully treated the disease by the injection of vaccines of organisms on the lines laid down by Sir A. E. Wright. He is unable to endorse the common opinion that extraction of the affected teeth arrests the disease, having seen an increase of symptoms after removal of a number of teeth, and this view is enforced by records of the opsonic index. He advised therefore, that only two or three teeth should be extracted at any one sitting.

Among interesting exhibits at Clinical Society the first place is due to one of congenital hypertrophy or giant growth of the feet, shown by the president, Mr. Clutton, who propose to amputate. The patient is a girl, now seventeen; her deformity was noticed at birth and increased slowly up to her fourteenth year. For the last three years the growth has been more rapid. The feet are now enormous, fairly equal in size. The whole left extremity is enlarged and nearly three inches longer than its fellow. Mr. Clutton proposes a Chopart operation for the shorter limb and a Syme for the longer one.

A case of enlargement of the clavicle and left side of lower jaw was shown at the same meeting by Br. Betham Robinson. It was in a boy of thirteen, and appeared of a chronic inflammatory nature. The swelling of the clavicle dated from a fall against a wall five months previously, that of the jaw from a toothache. There was also some enlargement of the right side of the thyroid, as to which Mr. Tubby remarked that he had seen such a condition of the clavicle secondary to a thyroid tumor. Mr. Robinson had given iodide with some benefit and he proposed to push it and also give mercury.

A woman of twenty-one, with hypertrophic osteo-arthropathy of the lower extremities, was shown by Drs. B. Shaw and H. Cooper. The patient was cyanosed, there was well-marked clubbing of the fingers, toes, and nose, swelling of both legs, due apparently to bony growths. There was a systolic murmur, but the lungs were free from signs of disease. The patient had always suffered from palpitation and breathlessness. Radioscopy showed both tibiæ and fibulæ to be enlarged, more markedly on the right side. There was uniform thickening of the lower two-thirds of these bones and irregular deposits at the attachment of periosteum to the interosseous membranes. The upper halves of the shafts of both femora showed similar changes, more marked on the right side. The other parts of the femora did not seem to be affected.

An infant of eight weeks was shown as an example of osteogenesis imperfecta, or more probably syphilitic. There had been fractures of thigh and leg bones and several ribs, which had united under mercury. The spleen was large, there was ulceration about the arms, and Dr. Sutherland, who showed the case, considered it most likely syphilitic, though it was suggested that it might be arrested development.

At the Medical Society a paper on the operative treatment of the ascites occurring with cirrhosis of the liver was read by Mr. Laurence Jones, who said the most suitable cases were those which had survived tapping of fluid, which was shown to be of mechanical rather than inflammatory origin. The common object of all operations was to increase the communication between the portal and caval systems, and the omentum was the portal area usually selected, and it was sutured to the abdominal wall outside the peritoneum. Various additional procedures had been suggested, but he did not advocate them. About one-third of the patients died within a month of the operation, another third were definitely improved, their lives being prolonged for some years in comfort. The other third were only slightly improved or not at all. The operation mortality should not exceed ten per cent.

One speaker thought the mortality depended on the case, not on the operation, as to which it ought to be *nil*. Another urged that the possibility of syphilis should always be considered, especially in the younger patients. Another remarked that in a febrile case, if the fever promptly abated under mercury, it was probably syphilitic. Another urged early operation, and yet another that success depended on the selection of the case.

Normal temperature, allowing for the fluctuations established by Ogle, Liebermeister, etc., seems not to be disturbed in its range by moderate changes of conditions in the health of individuals. Dr. Carter has reported to the Liverpool Medical Institute the results of observations made by the cooperation of the night nurses in his hospital. Each nurse towards the end of three months' night duty took her temperature, three-hourly, when not asleep in the day. The charts exhibited proved that the normal depression about 3 A.M., under ordinary conditions of life, also occurred after turning night into day for a period of about three months. The fall would, therefore, appear to be independent of changing conditions so far as these observations go.

Mental Hygiene in Childhood is the subject of an article in the new number of the *Westminster Review*, from the pen of Dr. Robert Jones, whose experience for some years at the Earlswood Asylum was extensive. He speaks of his interest in failures rather than successes as a reason for writing the article which is directed to the importance of a sound physical state in relation to mental development and activity. The child, he says, owes its possibilities to Nature, but the realization of them to nurture—the last term implying all those physical, mental, and normal agencies which surround the child, as well as those domestic, social, and scholastic influences brought to bear upon it. Such questions as maternal nursing and pure milk, he holds, concern both the state and municipality as does the feeding of poor school children, and he speaks of the improvement in the waifs and strays of our great towns on Canadian farmsteads. Speaking of lunacy his asylum experience tells him that the admissions are generally of persons poorly nourished and in impaired health, and as improvement takes place in the bodily state so does a simultaneous mental change occur. As a preventive of insanity he relies greatly upon the successful effects of societies which call attention to the hygiene of the young.

Dr. A. S. Myrtle, J.P. of Harrogate, died on the 29th ult., in his eighty-second year. He was M.D. Edin., 1844. He had been long identified with Harrogate and was a great authority on its mineral waters and the diseases in which they are most useful on which he had written prac-

tical brochures. He was consulting physician to the hospital, had been president of the County Medical Society, and also to the British Bacteriological and Climatological Society.

The death is also announced of Dr. Parcell of Manchester Square on the 1st inst. in his seventieth year.

Progress of Medical Science.

New York Medical Journal, April 13, 1907.

Atypical Phagocytic Cells in the Circulatory Blood.—M. R. Rowley enumerates the varieties of white cells found in normal or pathological blood as polynuclear leucocytes, lymphocytes, eosinophiles, mast cells, and myelocytes. The author has found cells quite different from those mentioned, in the blood of a patient with tertian malaria, and in three cases of lymphatic leukemia. In size and shape they vary much, but generally they are much larger than any of the usual blood cells. They are sometimes round in shape and sometimes irregular in outline, with protoplasmic processes. Pieces may break off, these resembling blood plates. They may have one or more nuclei which contain a fine reticular network, and in the majority of cells are kidney shaped. In the Wright modification of Leishman stains they resemble the large lymphocyte, the nuclei staining a reddish purple, and the protoplasm various shades of dusky blue. Occasionally reddish spots are scattered in the protoplasm, but in the majority of the cells there are no distinct granulations. The author presents illustrations showing the phagocytic action of these cells. As to their nature, they seem to resemble somewhat one of the elements found in exudates into the serous cavities, in the spleen, the so-called "endothelial cells."

Premature Detachment of the Normally Situated Placenta.—To three cases previously reported W. R. Nicholson adds two more, one recovering and the other dying. The general points in diagnosis are discussed and the author makes the following plea: First, that aberrant pain and unexplained bleeding, even if slight, during pregnancy should always suggest the possibility that placental separation is taking place. Second, that such cases should be watched with the greatest care. Third, that as soon as the provisional diagnosis is moderately certain, an active interference should be practised up to the point of the production of an amount of cervical dilatation sufficient for immediate delivery. Fourth, that in the rare cases in which the rigid unobliterated cervix is encountered, together with severe bleeding, valuable time should not be wasted, but that either a vaginal or a classical cesarean section should be performed according to the predilections and circumstances of the operator.

Milk as a Carrier of Infection.—C. Harrington says that the non-bovine diseases capable of being spread by milk are typhoid fever, dysentery, scarlet fever, diphtheria, and the so-called cholera infantum group of bowel troubles. The most important (excluding the bowel class) is typhoid. The author claims that the purchasing public is the element in the community which can correct the present faults in the question of milk supply in large cities. He says that it is the purchasing public that holds the key to the situation and can apply the remedy for all milk-borne infections; it is the man behind the dollar who can secure insurance against milk sickness by refusing to give any of it for milk as ordinarily produced and sold, and by a willingness to give a little more of it for the right kind. But no, the extra few cents daily appears to be an insurmountable obstacle, even to those who are free even to wastefulness in other ways; and they are content to buy dirt of all kinds, including cow dung and pus, with their milk, secure in the thought that by heating the mixture for a few minutes it is made much safer to drink. It seems unfair to the public and, in a business way, especially unfair to the clean dairyman, that dirty dairies should be permitted to exist; but the public is apathetic and will do nothing, and it appears that the only way to insure reducing milk-borne infection is State and municipal regulation of dairies and distribution.

Journal of the American Medical Association, April 20, 1907.

Protozoa and Disease.—C. W. Stiles discusses certain questions relative to the protozoa as disease factors, especially those at present somewhat disputed. He thinks the differences of opinion are largely justified, considering the difficulty of accurately defining the group. If zoologists can differ as to what are protozoa and what are not, certainly physicians and pathologists, to whom zoology is a side issue, can be excused for differing, and their difference of opinion, based on the imperfect present knowledge of the protozoa, are bound to be the most important factors in ultimately bringing out the truth. He defends the view, announced by him in 1901, that the diseases mechanically transmitted by insects are, with few exceptions, due to parasitic plants, particularly bacteria, and that those dependent on insects or other arthropods for their dissemination and transmission are caused by parasitic animals, particularly by sporozoa and worms. To this second rule he holds no exception has yet been proved. Such diseases as surra, which can be transmitted by inoculation, coition, etc., cannot be said to be biologically dependent on insect carriers, and he holds that this has not yet been proved to be the case with Rocky Mountain spotted fever or African tick fever. The claim made by Novy and Knapp that the parasite of African tick fever and of American spirillosis of chickens are vegetable rather than animal in their nature has more than impressed him, he says, but the possibilities of their transmission are not yet determined and these instances certainly do not disprove his rule. Stiles thinks that from what is known of the incubation period of yellow fever in a man and the life cycle of the microorganism in the mosquito and in man the biologic indications are that the specific cause is a protozoon; but he is in doubt as to whether it will prove to be a sporozoon or a flagellate. It is fortunate, he says, that the non-sexual reproduction of some of the protozoa is limited, as, were it otherwise, untreated malaria, for example, would be necessarily fatal.

Chronic Gastritis.—R. F. Chase remarks that chronic gastritis, understanding by the term a chronic inflammation of the stomach accompanied by pathologic changes, usually a diminution of the acidity with more or less impairment of the rennin and pepsin secretions and an excessive secretion of mucus, is a much less common disorder than is generally supposed. The diagnosis from the subjective symptoms merely, instead of by the well-known tests, is responsible for many incorrect diagnoses in the past. It is a disorder of rather long duration, often many years, more common in males. Ewald says that many patients said to die of old age, really succumb to gastric atrophy. Chase has not found evidence of this and his patients ranged between twenty and fifty years. It is impossible to ascribe it to any single cause, though alcohol has been considered as one of the most important. Chase agrees with Einhorn that loss of weight is not a usual symptom, the patients are often well nourished, appetite may be good, and pain, other than discomfort after meals, may be altogether lacking. Other symptoms that may occur are constipation, flatulence, eructations, etc., but no one symptom or set of symptoms is characteristic. Diagnosis must be based on the objective findings obtained by repeated examinations of the stomach contents and observation of the progress of the case. It seems that a rapid emptying of the stomach contents is rather common, and it is not positively determined whether this is due to hypermotility or to pyloric insufficiency. It is difficult to overcome and if, as some think, it is compensatory, hurrying the food into the intestine where most of the digestion is accomplished, it is better not combated. Chase thinks that most patients can be practically cured by measures to restore the hydrochloric acid secretion, care in diet and douches to free the stomach of the excessive mucus. Starches are better digested in the stomach in this condition than are proteids, and bearing this point in mind and remembering that all thermal, mechanical and chemical irritants are to be avoided, we have, he says, the key to dietetics in this disease. He advises lavage twice a week, using 30 grains each of sodium chlorid and sodium bicarbonate to a pint of water at 100° F. For the purpose of dissolving mucus and increasing the secretion, he uses from 10 to 15 grains of sodium chlorid and sodium bicarbonate in a glass of warm water to be taken about fifteen minutes before meals. Pepsin and hydrochloric acid are not relied on by him as agents to increase the hydrochloric acid secretion. Vacations and out-of-door occupations are important aids.

A Graphic Method in Practical Dietetics.—Irving Fisher proposes a new method of estimating the amount and proportion of proteids, fats and carbohydrates by taking, not units of weight, but units of food value as the starting point. This unit or standard portion is defined as that amount of food which contains 100 calories and a table is constructed which gives the weight of a standard portion of each particular kind of food, and out of the 100 calories contained therein, the number in the form of proteids, fats and carbohydrates. In order to carry out this method food should be served in standard portions or simple multiples of the same. Fisher has prepared a table, computed chiefly from the tables of Atwater and Bryant, and for made dishes from those of Kellogg. The main portion of his paper is devoted to the explanation of the use of this table and of a mechanical diet indicator which is figured and de-

scribed. By the apparatus thus devised the patient can avoid the necessity of having scales at the table, and after a little practice he can regulate his diet without any apparatus by simply exercising his visual memory of the same. The mechanical diet indicator was used for five months in an experiment on nine Yale students in the winter of 1906. No diet was prescribed and the indicator was used only to record the diet which the men themselves chose. It was found that by following Fletcher's rules as to mastication and obedience to appetite the men naturally and gradually reduced their proteids. The effect on their working powers was described in *Science*, November 16, 1906. Its value in pathologic cases has not yet been thoroughly tested, though one physician is reported to have found the apparatus of value in his practice.

Dilating the Gravid Uterus.—E. P. Davis describes the methods that are advisable in dilating the uterus in the later months of gestation for toxemia, placenta prævia and premature separation of the normally situated placenta. In the toxemic cases he does not include those due to the nephritis of pregnancy, but those of acute toxemia of hepatic origin with altered pulse tension, nervous disturbances of toxemia and the evidences of blood disintegration that accompany the condition. In such cases the uterus should be emptied as soon as consistent with safety, and for rapid dilatation he prefers bimanual dilatation with one or more fingers of each hand working synchronously in opposite directions, as most efficient. If unmanageable by the fingers, Bossi's dilator employed to one-half or two-thirds of its full capacity for from thirty to forty-five minutes with anesthesia has proved harmless and efficient. Except in rare cases, full dilatation with the instrument should be avoided. Vaginal Cesarean section is not favored in these cases by Davis, as he has never seen a case where he thought it clearly indicated. In many of these cases the patient is too far gone for anesthesia to be safe, and it should be avoided when pulmonary lesions are present. In placenta prævia the hand is also the best instrument for dilatation. As a rule the elastic bag is too slow in operation in these cases, as it is in toxemia. Bossi's dilator, Davis thinks, is a dangerous instrument to use in the vascular softened cervix of placenta prævia. In premature separation of the normally situated placenta, immediate delivery is called for, and Cesarean section, vaginal or abdominal, is the operation demanded. If this can not be done, multiple incision of the cervix followed by rupture of the membranes and dilatation by the hand as rapidly as is consistent with the integrity of the mother's tissues should be chosen. With the patient in good condition and not much hemorrhage, Bossi's dilators and the hand may be sufficient. The author emphasizes the importance of complicated cases of labor and the necessity of skilled and surgical assistance in such. The general practitioner should not depend on himself alone in these cases any more than he would in appendicitis or strangulated hernia requiring operation, and whenever possible such cases should receive attention in a hospital.

Multiple Aneurysm of the Aorta.—A. A. Eshner gives a very full account of a puzzling case which was first diagnosed as pleuritic, pericardiac effusion being also simulated. There were found on postmortem examination, however, five separate aneurysmal dilatations of the aorta, one of which had caused an erosion and penetration of the trachea. Pulmonary tuberculosis existed and was suspected during life, but the bacilli were not found in the sputum. No trace of pericarditis was found. The patient died suddenly of a hemorrhage which was entirely unexpected. The case is interesting as illustrating the possible difficulties of diagnosis, even by thoroughly competent physicians.

The Southern Maine Climate for Hypertonia Vasorum.—L. F. Bishop advocates the southern Maine coast as a climatic resort for persons suffering from disorders of the circulation due to mental overwork and worry. Such individuals show signs of chronic high tension in the arteries, which is followed later by cardiac dilatation and the well-known train of symptoms in these cases. A chronic vascular nervous overtone has been developed. He has seen such patients make satisfactory progress toward recovery in a single summer's sojourn in this region, which has a climate with an unusual combination of coolness and dryness. The recession of the coast makes the fogs, common elsewhere, infrequent, and the character of the soil is such that it very quickly dries. Excessive heat in summer is almost unknown. The pleasurable qualities of the southern Maine climate in hot weather are, he says, well known, but its advantages for this class of invalids should be better appreciated.

The Lancet, April 6, 1907.

The Pathology of Melanotic Growths in Relation to their Operative Treatment.—W. S. Handley describes the results of some of his work with pigmented growths arising in the skin. From examination of strips of tissue taken from the inguinal region of a cadaver containing a considerable number of melanotic growths the author concludes that (1) from the fairly regular distribution of skin nodules around the embolically invaded right inguinal glands it may be inferred that a process of local centrifugal spread, independent of the direction of the lymph current, took place around these glands as a focus. Examination of a radical strip of the parietal tissues extending from these glands showed (2) that permeation of the lymphatics is the principal agent in this local centrifugal spread, and that it occurs primarily and most extensively in the plane of the deep fascial lymphatic plexus. (3) Invasion of skin and muscle is due to upstream permeation of the lymphatics which carry lymph from these layers to the fascial lymphatic plexus. (4) Owing to the fact that arteries and veins usually run in close contiguity to lymphatic vessels, lymphatic permeation is followed by infiltration of the walls of the veins, and later of arteries, and by intrusion of the growth into the lumen of the blood-vessels. The importance of invasion of the veins with regard to pulmonary and systemic dissemination is obvious. (5) The order in time of these various events is deduced from the orderly sequence of processes seen as the strip of tissues is traced from its distal end towards the mass of glands which formed the local center of infection. (6) Regressive changes, due to inflammation excited by the growth, may occur in melanotic sarcoma.

The Area of "Acute Abdominal Conflux" and the "Incision of Incidence."—Under the former title C. P. Childe refers to an area located by the following rule: The esophageal opening of the stomach is situated behind the seventh costal cartilage, on the left side, about one inch from the sternum. A perpendicular line (a) is dropped from this point to Poupart's ligament. Then a line (b) is drawn from the right anterior superior iliac spine perpendicularly upwards to the lower border of the thorax. The author claims that within the area bordered by these two lines almost every acute abdominal crisis either must occur, or, as a matter of fact, does occur. He therefore terms this area the "area of acute abdominal conflux." It may be divided into upper and lower compartments by a horizontal line at the umbilical level. The incision which will lay bare this area is the vertical one midway between the lines (a) and (b), that is on just about the outer border of the right rectus muscle. This is the "incision of incidence" in an acute abdominal case. The advantages claimed for this incision are: (1) That it directly exposes to sight that part of the abdominal cavity which in a large proportion of cases *must* contain the offending organ, and which in another large proportion of cases does as a matter of fact do so. (2) That therefore in the large majority of cases it will enable the surgeon to deal directly with the offending organ, and without the necessity for any second incision unless this be required for drainage. (3) That for these reasons it makes, in the majority of cases, for the avoidance of delay and difficulty, two essentials of success in these operations, and will therefore give the best aggregate of results. (4) That in the minority of cases, in which it fails to expose the offending organ, the abdomen can be examined by touch just as well through the right semilunar as through the median incision. (5) That in those cases of intestinal obstruction where the patient can bear no more than the establishment of an artificial anus it is close to the seat of election for this operation—the cecum or lower ileum.

Amyl Nitrite in Hemoptysis.—G. A. Grace-Calvert does not think that any of the drugs usually given in pulmonary hemorrhages such as ergot, adrenalin, morphine, calcium chloride, or lactate, are of supreme value, though he admits that some of them may help if there is time for them to act. He places his faith in amyl nitrite. He carries three minim capsules of the remedy with him and breaks one, telling the patient to inhale the vapor quietly and regularly and not to be disturbed at the feeling of fullness in the head. The bleeding usually stops almost at once, though the patient may go on coughing up clotted blood which has been already effused. Later, if the patient is excited or alarmed, and the lungs appear to be irritable, he gives a hypodermic of morphine. The amyl nitrite produces such an immediate fall in the general blood pressure by dilatation of the vessels throughout the body that the pressure at the bleeding point is lowered and there is time for clotting to take place, and the hemoptysis usually ceases almost instantly. Even if the pulmonary vessels are dilated the ill effects are more than counterbalanced by the fall in blood pressure, and experiments seem to prove that it has a direct vasoconstrictor action on the vessels of the pulmonary periphery in spite of a vasodilator

action elsewhere. It may, however, be urged that this constriction of the pulmonary vessels is bad in that it must raise the blood pressure in those vessels, but this seems to be more than counterbalanced by the fall in general pressure, whereas in the case of adrenalin, ergot, etc., there is no corresponding fall in general pressure. Moreover, nitrite of amyl causes no reactionary pulmonary hyperemia (after the anemia), while adrenalin apparently does. Again, nitrite of amyl has a further good point, and that is the fact that it does not interfere with coughing and so does not place any obstacle in the way of the patient getting rid of the effused blood, and hence it considerably lessens the risk of septic trouble later.

British Medical Journal, April 6, 1907.

Coincident Embolism of Cerebral, Mesenteric, and Femoral Arteries.—T. R. Rodger reports the case of a woman of sixty-seven years who was seized with severe abdominal pain and soon began to pass blood by rectum. Four hours later it was noticed that the patient's speech had become indistinct and that there was a hemiplegia affecting the left arm and leg and the left side of the face. The discharge of blood had ceased, the abdominal pain was a little less, and the diminished rigidity rendered distinctly palpable a large tender swelling in the right iliac region. The question arose whether this might be an intussusception with secondary cerebral apoplexy due to straining, but the patient, who was quite conscious, said there had been no straining; the blood had merely trickled from her—indeed, she was uncertain from which passage it came—and examination of the blood showed it to be free from mucus. Moreover, the tumor had not the rounded outline of an intussusception, but was flat and extended more towards the middle line. The heart was rapid and irregular, and no distinct murmur could be detected, but five months previously the patient had been attended for a Pott's fracture, due to a fall, which she could not properly explain, but which seemed to be the result of a fainting turn, and at that time a mitral murmur was found. The diagnosis of embolism was further confirmed when, within a day or two, the right leg—the one unaffected by the hemiplegia—became cold and discolored with a bluish mottling from six inches above the knee downwards. No pain in this limb was complained of, but by this time the patient was semicomatose and could not feel pain. She died on the fifth day from the onset of the abdominal symptoms.

Sprains and their Consequences.—A. F. Shoyer reports the case of a man who fell on the doorstep. His right wrist was painful and there was a slight abrasion on the radial side of the joint. The patient applied lotions and carried the arm in a bandage and sling for two weeks before seeking advice. At that time the wrist joint was found swollen, red and painful. There was a small amount of fluid in it, and on movement there was distinct crepitus on the dorsal surface, which might or might not have been tendinous. A splint was applied, and two days later an *x*-ray photograph was taken, when it was seen that a large triangular piece of bone had been wholly or partly broken away from the dorsal edge of the lower or articular surface of the radius and projected above the dorsal surface of the bone. The splint was kept on for several days and both passive and active movements used every evening. The crepitus soon disappeared, and, movements being without pain, the splint was dispensed with at the end of a week. At the time of reporting the case the author states that, measured with the calipers, the anteroposterior diameter of the right radius at its lower end was about 1-4 inch more than that of the left. Flexion was slightly limited, and there was slight tenderness over the seat of fracture. It was expected, however, that full movement would eventually be secured at the wrist joint.

Iodine Spirit Catgut.—J. S. Riddell commends the use of iodine catgut, employing a solution of one part tincture of iodine to fifteen parts of proof spirits and keeping the catgut immersed eight days before using. He has used this material for ligaturing and suturing in hundreds of operations and strongly advocates it. He finds that it is sterile and antiseptic, loses none of its tensile strength in preparation, is readily and simply prepared, without any undue expense. All that is required is a glass jar, the solution above named, commercial catgut, and glass spools. The following suggestions are given: Ordinary glass tubing about the thickness of the little finger should be cut in lengths of two inches. This is long enough to take one length of Hartmann's catgut in single layer without knotting. The catgut must be tightly wound on the tube, or, what is better, the tube should be rolled into the catgut. The catgut is first fixed, either by tying it through or round the tube, and when wound on is fixed with a slip loop below the last turn. The spools are immersed in the solution and are kept there indefinitely till they are to be used. They must not be used till the eighth day after immersion, and for guidance the date of immersion and the size of the catgut should be noted on a small label on the side of the glass jar. The author finds No. 2 catgut most useful for ordinary purposes, and a larger supply of it should be prepared than of the other sizes. If many spools are immersed in one jar and are not used for some weeks after immersion, it is well to add fresh iodine spirit solution at intervals of two to three weeks, so that one may be certain that there is always an excess of iodine bathing the catgut. Finally the catgut is absorbed completely, but only after it has subserved its purpose.

Hughling Jackson's Views of the Functions of the Cerebellum.—V. Horsley reviews the opinions of Hughlings Jackson with reference to cerebellar functions as illustrated by recent research, and gives a brief résumé of the various steps by which we have come to our present knowledge. He contends that all research, both ancient and modern, confirms the view that the cerebellar cortex is the first chief station of representation of the afferent basis of all the skeletal muscles. He notes that in determining cerebellar effects due allowance must be made for accompanying influence of the cerebrum and of the spine. The cortex cerebelli and the nuclei cerebelli must be considered as two distinct organs. Naturally nothing particularly new is brought forward in such a paper as this, but it serves as an interesting commentary on the gradual and logical development of the views of the distinguished English neurologist.

Berliner klinische Wochenschrift, April 1, 1907.

Injections of Oxygen into the Knee-Joint.—Rauenbusch employed the injection of chemically pure oxygen into the knee-joint for the purpose of obtaining a better *x*-ray picture, as recommended by Werndorf and Robinson a few years ago. He was surprised to find that patients suffering from chronic joint diseases requested a repetition of this procedure, as it brought them so much relief from their pain. The experiments were continued and a number of cases of chronic arthritis and arthritis treated by this means with very favorable results. The gas was injected through a small canula under strict aseptic precautions, directly into the cavity of the joint. The intervals at which this was done varied from one to three weeks. In the presence of a synovial tuberculosis, the method was also attended with good results. The treatment is entirely empirical and the author is not prepared to state whether its effects have any permanent value, but recommends its use in selected cases as a means of alleviating the distressing symptoms.

A Contribution to the Treatment of Hay Fever.—Heymann publishes his experiences with the administration of thyroid extract in this disease. He examined a large number of cases and found that these patients are no more apt to be afflicted with nasal deformities than a corresponding number of others who are free from the attacks. He did find, however, that if the obstructions in the nares were removed a marked improvement always occurred. The best results with drugs were noted with the administration of thyroid extract. He gave this in tablet form, one to three daily, each containing 0.3 gm. of thyroid substance. The improvement in twenty-one cases was very favorable, and although no conclusions are possible as to the etiology of the disease the writer thinks that it is probably dependent upon a nervous diathesis in the domain of the sympathetic nerves. In a considerable number of the patients who were under treatment for the disease he found an enlargement of the thyroid gland, although not of sufficient extent to demand treatment for itself.

Congenital Stricture of the Urethra.—Posner calls attention to the possibility of this occurrence, although from the general prevalence of gonorrhea one is led to attribute almost every case to this source. It is possible that many cases of incontinence in children are due to this cause, where the lesion may be situated not only in the anterior portion of the urethra, but also at the junction between the membranous and bulbous portions. Posner reports a case of urinary retention in a boy eleven years old, which disclosed on passage of the catheter an obstruction in the region of the bulbous portion. The boy had been afflicted with enuresis and also occasional attacks of hematuria. Improvement followed gradual dilatation with elastic catheters.

Münchener medizinische Wochenschrift, March 12 and 26, 1907.

The Avoidance of Perineal Lacerations During Labor.—Toff discusses a method for preventing this accident which is very easily carried out. It depends on

keeping the head flexed as much as possible until the greater part of the occiput is delivered before allowing extension to take place. The less the occiput is permitted to come out under the symphysis the greater the sagital diameter of the child's skull which must come through the vulva. The delivery, as advocated by the author, necessitates the lateral position on the part of the patient. The hand of the attendant is placed on the occiput as soon as this appears, and then the latter is pressed down and pulled out both during and between the pains. By this means flexion is increased, and when the neck is engaged under the arch, then extension may be permitted to take place. By this procedure the writer claims to have saved lacerations in many cases where rigidity of the soft parts and a narrow vulvar outlet would have resulted in a tear.

The Alexander-Adams Operation.—Spaeth calls attention to the fact that in Germany this operative procedure is not appreciated as fully as it should be, notwithstanding its many advantages. It is applicable in cases where a more extended operation is impracticable or unnecessary, as in a virgin where a simple retroflexion without any descent may serve as the basis for a very severe reflex neurosis. It is also applicable in sterility and numerous instances have been recorded of its successful application in such cases. The writer reports a series of fifty cases in which a modified Alexander-Adams operation was done. Thirty of these were accessible for subsequent observation and in all the uterus was in a normal position. Pregnancy had occurred in ten of these women and in four instances it had taken place twice. In only four cases, however, did the pregnancy continue to term, and although this would lead one to attribute the abortions to the operation the author is of the opinion that the accident was due rather to the presence of an endometritis and most of the patients had already aborted at different occasions before the operation. The fact that only one-third of the patients became pregnant at all may be ascribed to the age at which the operation was undertaken. The labors were all normal, without any particular pains in the groins. The round ligaments, when doing the operation, should be shortened about 8-10 cm., and the writer thinks that many of the failures are due to excessive shortening.

Ocular Paralysis After Lumbar Anesthesia.—Ach reports four cases of abducens paralysis occurring in a series of 400 patients where lumbar anesthesia was employed. In three of the patients there was a unilateral and in the other a bilateral paralysis. This appeared on the fourth to the eleventh day after the operation and lasted anywhere from eight days to three weeks. In all these cases there were present severe headaches, pains in the back, and restlessness, and the anesthetic effect was either very brief or absent altogether. A comparatively small number of similar cases have now been reported by other authors, and from a study of the subject Ach has formulated a theory for the production of this paralysis of the abducens muscles. He believes that the latter depends on the direct action of the toxic material on the nerve rather than on its nucleus in the fourth ventricle. The phenomenon is similar to the paralysis of respiration seen in other cases, where the condition is also due to a direct action on the phrenic nerve rather than on the respiratory center in the medulla. In order to avoid the possibility of this complication, the writer advises the use of the most harmless preparations for the injections. The anesthetic should be used in the smallest possible doses and in a weak solution. Absolute rest on the back is essential, with the trunk raised.

Healing of a Carcinoma by Sunlight.—Widmer refers to the good results obtained in chronic ulcerative processes by exposure to the direct rays of the sun, and details a remarkable cure observed in a woman of eighty-one years who presented a circumscribed epithelioma of the back of the hand. Operative treatment being refused, the lesion was exposed to the sunlight for several hours daily, and after a period of three months the ulcerated area was completely healed, and remained so. The writer found that reflected light apparently increased the efficacy of the direct rays for the purpose indicated.

Deutsche medizinische Wochenschrift, March 21 and 28, 1907.

The Intravenous Administration of Strophanthin.—Starck places the three requirements of an ideal cardiac stimulant as follows: a selective action on the heart without the production of harmful after-effects on any other organs, ease and certainty of dosage, and lastly a rapid effect. Digitalis has usually been accepted as the standard drug for the treatment of cardiac condition, but it cannot be said to completely fulfill all of the requirements. Endeavors have repeatedly been made to overcome its disadvantages by the introduction of preparations of its various active principles, which could be used subcutaneously. It was found, however, that such preparations were not readily soluble, and caused a great deal of pain at the site of injection. When a more soluble preparation of digitalis was finally obtained, the intravenous injection was proposed and carried out with good results. Strophanthin was similarly employed, and with equally good, if not better results. Starck reports seven cases of acute and chronic cardiac disturbances, all of a severe character. The only bad result was in a case of advanced sepsis, which was practically hopeless at the start. The dose varied from 0.005 to 1.25 gm., advancing with caution from the smaller to the larger amount. There were no evidences of any after-effects, nor was any cumulative action noted. A well marked sedative action was absorbed after the injections, which relieved the patients greatly. Starck thinks that this sedative action is manifested on the central nervous system. The effect on the pulse seems almost immediate, and the dyspnea, if present, is relieved. The strophanthin injections may be recommended as the most efficient form of treatment for the purposes indicated.

Intermittent Articular Hydrops.—Kamp calls attention to this peculiar condition for which no remedy has apparently been found. The term is applied to a recurrent swelling which affects more particularly the knee joints, and is quite rare. In Kamp's case it was present in an elderly lady in whom the swelling came on at regular intervals of from five to nine days. The acute swelling came on within twenty-four to thirty-six hours, lasted about two or three days, and then gradually subsided. There is no fever present in these patients and very little pain. The writer thinks that the complaint has nothing to do with rheumatism or gout, as is commonly believed. Its exact cause is as yet unknown, but it probably depends on a trophic vasomotor neurosis of the joint The condition is very chronic, but may disappear for a time, thus simulating a period of cure. Treatment has thus far proved valueless, at least the use of water and bath cures, the salicylates, quinine, arsenic, etc., have not had any effect on the course of the disease.

Spirochetes in Framboesia Tropica.—Mayer confirms the findings of Castellani as to the presence of spirochetes in this tropical disease, the clinical similarity of which to syphilis has been noted by a number of writers, although no actual identity has ever been demonstrated. Mayer found in five cases of framboesia in Ceylon and Eastern Africa the typical form of spirochete described by Castellani, which closely resembles the *Spirochæta pallida* discovered by Schaudinn. The organisms were found in the serum from recent papules. Mayer claims that these spirochetes are the probable etiological factor in the production of this tropical disease.

Contusion Pneumonia.—Litten discusses this form of pneumonia, of which a considerable number of instances have been described, and which differs from the so-called traumatic pneumonia, in that there is no wound of the lung by the penetration of objects from without. The injury is due to a blunt force and produces a sudden and extensive compression of the pulmonary tissue. No evidence of any injury can be detected on the outside of the chest, although this may have been sufficient to have caused a complete tear of one of the lobes of the lung. Ecchymoses are more likely to be found in cases where the lungs have escaped injury. The pneumonia need not necessarily occur at the site of the external injury, but may take place in the opposite side of the chest, and if there are any old adhesions or tubercular foci present these act as a locus minoris resistentiæ. The lesion is most often the result of a fall from an elevation, but it may also be produced by a severe blow, by compression, or by being run over. Another cause to which the writer calls particular attention is the lifting of heavy weights, an instance of which he reports in the present paper. A man engaged with a number of others in lifting a heavy truck was soon after seized with severe pains in the chest, and was prostrated. Two days later a pneumonia was diagnosed, and within five days the man was dead. Three other similar cases were previously observed by the author, from which it appears that the cause referred to is an important factor in the etiology of the condition. The chief characteristic of this form of pneumonia is its sudden onset, brief course and high mortality rate, for as far as can be determined from the cases thus far reported the latter is apparently about 68 per cent.

Book Reviews.

Pulmonary Tuberculosis. Its Modern and Specialized Treatment, with a Brief Account of the Methods of Study and Treatment at the Henry Phipps Institute of Philadelphia. By Albert Philip Francine, A.M. (Harv.), M.D. (U. of P.), of the Staff of the Henry Phipps Institute, Philadelphia; Examining Physician to the White Haven Sanatorium; Instructor in Medicine and Physician to the Medical Dispensary of the University of Pennsylvania; Medical Registrar to the Philadelphia Hospital. Philadelphia and London: J. B. Lippincott Company, 1906.

This work contains a considerable number of facts and no inconsiderable number of unproved theories regarding pulmonary tuberculosis. It would appear from a perusal of the chapter on "Hints and Helps to Tuberculosis Patients" that this work is intended not only for medical men but for the tuberculous laity as well, and there is scarcely a doubt but that the layman will be interested and edified (?) to discover, as the author so frequently points out all through his work, what an ignorant, unscrupulous, careless, and altogether mischievous individual is the general practitioner of medicine when he comes to deal with the problems of tuberculosis. Indeed, the general practitioner does not alone suffer from the author's criticism. For instance, in the chapter on "Climate" (page 47) occurs the following: "Poor people often make a financial effort and pay one visit to some well-known physician for an opinion or diagnosis. The latter finds them suffering with tuberculosis, usually well advanced, and with self-complacent irresponsibility advises them to 'go out West.' He may even go so far as to tell them that in this course lies their only chance of getting well. Such advice cannot be too strongly condemned, both from a professional and humanitarian standpoint." Again in the same chapter one can imagine the feelings of the layman who has heretofore reposed some measure of confidence in the medical profession when he reads as follows: "Certainly one cannot condemn too strongly the advice so commonly given, founded on false conceptions, ignorance, and irresponsibility—to go away, live out of doors, take plenty of milk and eggs, and not 'overdo' exercise. Those who follow such unfortunate and reprehensible advice, and there are many thousands who do, are victims to the ignorance of the profession, and are hourly frittering away their chances of recovery." Yet, this does not seem such unreasonable advice—to "live out of doors, take plenty of milk and eggs, and not 'overdo' exercise."

The lengthy "Prefatory Word" under which title the author introduces his subject, is not merely prefatory but fundamental. Though on the whole most of the author's statements, when he is not attacking the members of his own profession, are no doubt sound, they are unconvincing because, on the one hand, of the dogmatism which characterizes the work throughout, and, on the other, of the haphazard manner in which the thoughts are grouped, and again because of the fact that some statements which must strike many as embodying entirely new ideas, are made without the least reference to authority.

In the chapter on "Koch's Tuberculin" and in that on "Serumtherapy" the author has exercised much better judgment and exhibited comparative freedom from the assertiveness and dogmatism which characterizes the rest of the book, but two chapters of sound, unprejudiced, good reading cannot serve as justification for the balance of the book which contains but little that is new or instructive on the subject of phthisis.

The Nervous System of Vertebrates. By J. B. Johnston, Ph.D., Professor of Zoology in West Virginia University. Philadelphia: P. Blakiston Sons & Co., 1906.

The author's own view of this work is given in the preface: "The attempt has been made in the following pages to give an account of the nervous system as a whole, to trace its phylogenetic history, and to show the factors which have determined the course of evolution. The functional point of view which is the chief characteristic of the present book, brings the treatment of the nervous system into close relation with the work of recent years on the behavior of animals." Dr. Johnston has had before his mind at all times the fact that the inherited organization of the brain is actually the product of the experience of the genus, species, and variety (sometimes), and of the individual parents, although of these last the influence is but small; that the brain as inherited by the individual man contains the results of untold ages of experiences, the experiences of the individuals who are a given man's progenitors, for example, which experiences at times reach the plane of the individual consciousness, and we recognize them as instincts or prejudices, which instincts and prejudices we but too well know as forces impelling, and sometimes compelling, us to action.

Syphillis du Poumon, chez l'Enfant et chez l'Adulte. Par le Dr. Bériel, ancien interne des hôpitaux de Lyon, préparateur au laboratoire d'anatomie pathologique. Paris: G. Steinheil, 1906.

This volume is a capable summary of our present knowledge of pulmonary syphilis, and contains an extensive bibliography of the more important publications bearing on the subject. The author studies in detail the gross and minute pathology of the various lesions, and their associated symptoms. He is very cautious in his acceptance of reputed cases, rejecting many of those reported as being tuberculosis occurring in a syphilitic subject. A few pages at the end of the volume are devoted to the results of treatment, the technique being omitted, as out of place in a special work of this nature.

Animal Micrology. Practical Exercises in Microscopical Methods. By Michael F. Guyer, Ph.D., Professor of Zoology in the University of Cincinnati. Chicago: The University of Chicago Press, 1906.

When Kölliker's Microscopical Anatomy appeared in English the only reagents in common use, so far as anything in the references to technique told the reader, were 5 per cent. solutions of caustic soda, a solution of acetic acid of the same strength, and a solution of chromic acid of a strength not definitely given. Frey's Microscopical Technology, translated by Cutter and published in the '70's, tells us in the preface that the methods of technique have become so numerous that they must be discussed in a volume other than one given up to the description of the tissues. But to-day, if one wishes to keep up a working knowledge of general technical development outside of his own small special field, a whole library is in demand. This fact is well illustrated in this admirable handbook which, so far as certain matters are concerned, leaves but little, if anything, unsaid.

Chapters 1 and 2 give a broad general view so that the beginner can see the end for which he is working, and Chapters 3 to 6 give an accurate insight to the way of handling the great development of modern technique, the section, the consecutive section, and finally, reconstruction to scale. Chapter 3 gives methods of killing and fixing, but omits the morphine method in reference to microscopical animals which in many instances is notably better than that with chloroform water or its substitute.

Then follows an exhaustive discussion on the processes of sectioning, the paraffin, celloidin, and freezing. There is no mention of the Bumpus modification of celloidin methods, which are truly admirable. The student who has mastered these chapters has also mastered the whole essential technique of sections and is to be congratulated accordingly. The discussion of stains and reagents is accurate and generally sufficient, but the technique described suggests a special interest in the nervous system. Appendix C is important, as it gives in full detail the best method of hardening and preparing every tissue of the body.

Diseases of Children. A Manual for Students and Practitioners. By George M. Tuttle, M.D., Attending Physician to St. Luke's Hospital; Martha Parson's Hospital for Children; Bethesda Foundling Asylum; and Professor of Therapeutics, Medical Department of Washington University, St. Louis. Series edited by Bern B. Gallaudet, M.D. Second Edition. Revised and Enlarged. Illustrated with five plates in colors and monochrome. Philadelphia and New York: Lea Brothers & Co.

Most books dealing with diseases of children can be divided into two parts; the first consisting of chapters on the special conditions of infancy and childhood, and the other treating of practice in general, but slightly modified to suit the requirements of young patients. The first part is, by far, the more important; and it is usually much the smaller of the two. In the present volume, this first or introductory portion consists of about sixty pages, and contains chapters on the infant at birth, normal development of the infant, examination of the child (one page only), diseases of the new-born infant, and the feeding of infants. This last chapter, which is probably the most important in the book, is clearly written, and deals ably with the subject. The remainder of the volume is concerned with the various diseases, arranged as in books on general practice; but following Diseases of the Digestive System there is another valuable chapter on Disorders of Nutrition, dealing with malnutrition, marasmus, scorbutus, rachitis, diabetes, and rheumatism. The book is well adapted to the requirements of the beginner in the study of pediatrics.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Regular Meeting, Held April 4, 1907.

THE PRESIDENT, DR. JOHN A. WYETH, IN THE CHAIR.

THIS meeting was held under the auspices of the Section on Public Health.

Street Dirt and Public Health.—Dr. W. GILMAN THOMPSON said that it should be admitted that the noxious influence of such dirt upon the human organism might constitute a predisposing cause of disease by maintaining a constantly irritated or congested condition of the respiratory mucosa, quite as much as it might act as a medium of the direct conveyance of disease germs. Street dirt he regarded as comprising any or all of the following ingredients: (1) The ashes, house sweepings, etc., which were freely blown about from exposed ash carts and ash barrels; (2) the excrement of horses and dogs voided in the streets, to become dried, pulverized, and distributed by wind and traffic; (3) the irritating, powdered asphalt, ground from the surface of the pavements, and often mixed into a slimy paste with mud, horse dung, and the petroleum drippings from automobiles; (4) pulverized earth, plaster, iron dust, cement, etc., derived from buildings undergoing construction or demolition, and carried about the streets in loosely constructed wagons; (5) the earth from street excavations, usually impregnated with sulphides and other products from leaking gas mains; (6) the soot from chimneys which eventually settled in the streets; (7) the garbage which, in the tenement districts, was frequently overturned into the street; (8) human excreta which, in the crowded tenement neighborhoods, was often voided by children or adults in blind dark alleys and ill-lighted streets. It was no exaggeration to state that nine-tenths of the diseases of this type, *i.e.* the acute inhalation diseases and chronic catarrhal diseases, were directly due to dirt inhalation. During the winter the masses of dirt-covered snow melted slowly and so modified the local climate by begetting moisture and chilliness of the atmosphere, which favored the development and maintenance of coughs, colds, and rheumatism. The sewers became clogged with street refuse and the crossings were often left ankle-deep in slush, making it impossible to keep the feet dry. In the tenement districts where the street life constituted so large an extension of the house life, the condition of the streets was most important from a social, moral, and economical standpoint. Articles of fresh food, such as milk, fish, vegetables, and fruits, were more or less exposed to contamination by street dust and coated with bacteria. As long as dirt remained moist it was relatively heavy but also sticky; this favored its being carried into dwellings, public buildings, street cars, and subways, there to be dried and pulverized. Dry dirt remained comparatively harmless while at rest. But in the streets it seldom remained at rest. The longer dry dirt remained in a given street, the more it became pulverized and the more widely was it disseminated in the atmospheric air. Sufficient nonspecific germs were conveyed by street dust to excite catarrhal or purulent inflammations, and by thus fostering a chronically diseased or irritated condition of the respiratory passages, the latter were rendered liable to more serious infections. Herein lay the chief menace to health from street dirt. The danger was complicated by the fact that the sputum of patients having chronic tuberculosis, bronchitis, or nasopharyngeal catarrh, expectorated when they were at large in the streets, was swept from the sidewalks and added to the general street dirt. Dr. Thompson said that one of the great difficulties in obtaining permanently clean streets in New York City appeared to reside in the multiplicity of authorities controlling them. Such a degree of subdivision was doubtless necessary in these days of extreme specialization in all classes of labor, but unfortunately it left a loophole of escape from complaints by shifting the responsibility perpetually from one department to another. Dr. Thompson submitted the suggestion that after further discussion of this important topic a resolution be acted upon to the effect that:

Owing to the accumulation of street dirt in this city, the health of many citizens was impaired so as to render them frequently and unnecessarily subject to serious and often fatal respiratory diseases, and that in order to secure permanent improvement in street cleanliness, the Mayor of the city be urged to appoint a commission to study and report upon the matter and formulate a proper scientific plan for permanent relief from conditions which afforded a constant menace to health, as they now existed.

Such a commission would consider the whole subject from its medical aspects as well as its engineering problems, its economic side, its administrative efficiency and responsibility, and its permanence. Its report would furnish an appropriate basis for legislation and secure permanent relief.

Practical Difficulties in Cleaning the Streets of New York City.—Capt. F. M. GIBSON, late Deputy Commissioner, Department of Street Cleaning, New York City, addressed the Academy on this subject. He said that after hearing Dr. Thompson's paper, he must enter upon a defense of the Street Cleaning Department. The matter of cleaning the city streets and keeping them clean must necessarily be predicated upon a number of prerequisites. First, the streets must be properly paved to be properly cleaned, as broken places made perfect cleaning absolutely impossible. In a city so congested as was New York, so crowded with traffic, there were limitations which made this a serious problem. In a conversation with President Ahearn he was told that between December 17 and March 17 there were but nine days when the asphalt could be repaired. Another prerequisite rested with the people themselves; it was necessary to have the cooperation of the public in observing the city ordinances. Many people swept the pavements into the streets after 8 o'clock in the morning, and orange, lemon, and other skins were thrown into the streets. Another obstacle to street cleaning was the restricted use of water; there should be a free and unrestricted use of water and when the weather conditions permitted, street flushing. Capt. Gibson said that if the Academy was going to make any recommendations, it was very important that the unrestricted use of water, when available for the purpose, should not be denied the Street Cleaning Department. He was a firm believer in flushing the streets. Another prerequisite was the earnest and hearty cooperation of the city departments which for some cause or causes seemed to be seriously lacking. This remark applied with special force to the city magistrates who, through kindliness or good heartedness perhaps, were much too lenient with old and persistent offenders. He said that so soon as the Bingham Police Bill was passed and became a law, it would be an excellent thing to discontinue the Board of City Magistrates and then to turn these old offenders over to the police captains of each district. They would be made to do their duty. Another important thing and serious obstacle to proper street cleaning was the licensing of pushcarts. There should be a discontinuance of pushcart licenses. As long as this was practised, and this kind of traffic was permitted, it would be absolutely impossible, especially on the lower East Side of the city, to keep the streets in anything like a sanitary or cleanly condition. The city would save about $70,000 a year by their discontinuance. The city of New York should not be placed at such an expense. There were approximately 5,000 pushcarts in New York City; each one must have a license which cost $2; thus the city only obtained $10,000 a year. Another prerequisite was the

maintenance of the strictest discipline possible, for, without it, in such a large aggregation of men, one's best efforts counted but for very little. More positive rules should be made, and if a man broke one he should be dismissed for good, and not be allowed to come back to the Street Cleaning Department, or any other. Another prerequisite was the total elimination of politics. Another was the definite fixing of responsibility for the furnishing of proper receptacles for refuse, and the necessary number of them, especially in the tenement house districts. The law required that they be filled only to four inches of the top; instead of this they overflowed and became scattered. Another prerequisite had to do with permits for building material. New York City in recent years had grown to be a city on top of a city; therefore, the work of cleaning the streets should be conducted on broad, bold, intelligent, and common sense principles, and, to do so, the laws governing such work should be as elastic as the honest interest of the city would permit. For instance, broader civil service regulations, extension of the Commissioner's powers in selecting officers of the uniformed force, etc. He should also have greater latitude in procuring the necessary supplies for his department. Captain Gibson then gave a few statistics which he thought might be of interest in regard to the quantities of material collected and disposed of.

Cart Loads, 1906.

Mechanics and help	219
Engineers, firemen, etc	25
Total	5,601

Captain Gibson closed his remarks by suggesting a practical change of municipal government, eliminating the boroughs and their machinery.

Practical Ideals of Street Cleaning—Mr. Rudolph Hering read this paper. He said that under practical ideals of street cleaning they should understand the nearest approach that could be expected from a modern municipal government, to keeping the streets of a city perfectly free from the accumulation of all kinds of dirt, which might propagate disease, be unpleasant or annoying to them, or injure property within buildings. Such dirt consisted chiefly of finely comminuted solid matter or dust, originating both in the houses and in the streets, or dragged into the city by conveyances, animals, or pedestrians, or blown into it by strong winds. Ashes, garbage, and rubbish were excluded from his discussion. The street dirt or dust consisted of organic and inorganic waste matter and was traced to the following sources: Buildings, pedestrians, horses and wagons, earth working up between pavements or paving stones, small litter, and dust and soot carried by the winds. Asphalt and wood generally gave the best satisfaction in keeping down the quantity of dirt generated upon the streets, and from their comparatively smooth surfaces allowed of the most perfect cleaning. A good, even, and smooth pavement, laid upon a firm foundation, was the first and most important practical ideal for street cleaning. He emphasized the importance of having narrow joints for stone blocks. The second most practical requirement for the best practical street cleaning was water. In some European cities some of the most important asphalt streets were washed daily with hose, connected either directly to the water mains or to a water truck. A squeegee, having a blade of rubber, was used to scrape the material thus loosened from the center of the streets to the gutters, where it either entered the sewers, as in Paris, or its water was allowed to drain away, as in Berlin, and the dried material was then carted away. With generally good grades for sewers, as in New York, there appeared no good reason why the Paris method should not be applicable here, except that a large amount of road detritus or silt would be deposited in the rivers near the sewer outlets and later require removal by dredging. Naturally all street cleaning with water was not applicable during freezing weather, but it had been demonstrated that if the streets were clean when winter began, and if the snow was promptly removed and no rubbish was cast upon the streets, there was no objectionable accumulation during the winter and no special cleaning was required until flushing or sweeping could be resumed. Another important requirement for perfect street cleaning was sweeping. On most of the streets of large cities the dirt was now removed by machine sweepers. The greatest defilement on busy streets came from the horse droppings; it was necessary to scoop them up as soon as possible after dropping and to deposit them into dust bins situated at convenient places, or into portable receptacles immediately at hand. Another important requirement to secure practical street cleaning related to the organization for effecting it. To do the best work in the shortest time and at the least expense meant high efficiency on the part of the managers and workmen. In conclusion he suggested that a careful and thorough collection of facts be made by the city covering this service in other principal cities of the United States and Europe, and basing it on properly comparable elements so that definite and practical conclusions were clearly indicated by them as to the best means for securing the highest attainable degree of cleanliness.

Dr. Francis P. Kinnicutt said he wished to emphasize the importance of the hearty cooperation of the public in the work of street cleaning. An ordinance against throwing litter in the streets was not sufficient. He remembered that Col. Waring said that a great deal of his success in keeping the streets clean was due to the cooperation of the citizens of New York; he was able to develop in them a civic pride. With regard to this civic pride, if 1,000 citizens should take a daily interest in street cleaning, as they saw it done before their own doors, and would give their ideas, or observations of defects or faults, much might be accomplished. It was preposterous to say that it was impossible to clean the streets of New York, or that this city should be less clean than the cities of Great Britain, or continental Europe.

Dr. S. A. Knopf said that to sweep a street when it was dry was a crime against one's fellowmen. It was a mistaken idea to think that dust which did not contain pathogenic, *i.e.* specific disease-producing microorganisms, was harmless. It was on the contrary most harmful, because of its irritating influence on the mucous membranes of the respiratory organs. The relative increase of tuberculosis among the New York street sweepers which was first noticed a few years ago was, in his opinion, not solely due to the inhalation of tuberculous sputum which might have been expectorated in the streets by consumptives and which had most likely been rendered innocuous

by sunlight and air; but it was due to the irritating influence of dry dust, raised by the street sweepers themselves, because they did not sprinkle the streets before sweeping. The pulmonary tissue thus irritated invited an invasion of the bacilli to which the street cleaner, in his unsanitary tenements and other unhygienic environments, was as much exposed as anybody else. When the streets were sprinkled before they were swept there would be less tuberculosis among the street cleaners. As proof of all this he cited the well known fact that the street cleaners of Berlin were the healthiest body of men of all the city's employees and virtually free from tuberculosis. Much had been said of cooperation between the various departments and the citizens at large. He approved of this most heartily, and even went a little further and said that they should not only have the cooperation of the adult citizen, but also that of the young rising generation, and should teach them civic pride. Some would perhaps recall the excellent service rendered by cooperation of the children, which was brought about by the late Col. Waring when he was at the head of the Street Cleaning Department. However, they needed above all things the cooperation of the corporations, surface and elevated street car companies, and all corporations who now constantly violated the law by burning soft coal. If these corporations would do their duty and obey the laws, there would be less dust in the air, less dirt in street cars, and less dust swept down from the elevated platforms on the pedestrians by the ignorant or wilfully careless porter. Lastly, there should be a training school for street cleaners as well as there was one for policemen and firemen, and the advancement in the ranks should not depend upon anything but practical knowledge of street cleaning and the record as to the performance of duty in previous positions. With trained sanitary engineers at the head, practically trained foremen and practically taught men in the ranks, a cooperation of all the city departments interested in the work, a cooperation of corporations, citizens at large, young and old, they should have as clean a city as any in the world.

Dr. T. R. Maxfield believed that the danger from street dirt was due more to the irritation produced than to any specific infection. One of the first things that struck him was the matter of educating the inhabitants, especially in the tenement districts, to keep dirt, ashes, garbage, etc., in proper receptacles. He believed the streets could be cleaned at night; the night air was heavier and was less conducive to the spread of the dust through the air. The ashes should be removed at night. Pushcarts should be abolished. A lack of cooperation of the different departments was a serious thing of to-day. There should be a more hearty cooperation of the police in enforcing the sanitary ordinances; it was now a dead letter. There should be proper cans for ashes and garbage. In Brooklyn this was being enforced as rapidly as was possible.

Mr. G. A. Soper agreed that the injurious effect of dust was due more to the irritating effects than to its microbic character. It was very necessary to get rid of the waste in the houses. A large quantity of street dirt was carried away by the sewers and rivers; the rivers finally became the depositories of this waste. The Department of Docks removed from between the slips and piers over 870,000 cubic yards of material, a large part of which came from the streets, carried there by the waters in the sewage. The cost of this was not far from $200,000. The government would be forced to continually dredge these channels in order to permit the ocean-going vessels to get by. It had recently been proven that the garbage that was emptied into the middle and upper bay had not been carried out to sea; most of it was not carried beyond the narrows. Again, much of this garbage came back. After the houses on Barren Island were destroyed by fire, the refuse was carried fifty miles beyond the New York harbor and, it was found, this garbage littered the coast of Long Island for fifty miles and the coast of New Jersey for seventy-five miles, some going even to Atlantic City.

Mr. Baker said that street cleaning was as important as was garbage disposal. He said that one of the great faults of American cities was the large amount of money expended in municipal works and the comparative neglect in their maintenance after. This applied particularly to the care of the street pavements.

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held March 25, 1907.

The President, Dr. Walter Lester Carr, in the Chair.

Report of the Comitia Minora.—Dr. John Van Doren Young read this report and recommended the dismissal of the charges of malfeasance in office against the counsel of the society, Mr. Champe S. Andrews, by Dr. Charles J. Mooney. After a discussion, partaken in by Dr. Egbert Le Fevre, Dr. John J. MacPhee, and Dr. Samuel Lloyd, the motion was lost. A motion was then made that the charges against Mr. Andrews be considered at a special meeting of the society; this was carried.

Multilocular Glandular Cystoma of the Ovary Complicating Pregnancy.—Dr. B. S. Talmey presented this clinical report, which showed that large tumors did not always produce dystocia (to be published later).

The papers of the evening were devoted to a discussion on gonorrhea in women.

Pathology of Gonorrhea in Women.—Dr. Henry C. Coe read this paper. (See page 684.)

Infection of the Urethra, Vagina, and Glands of Bartholin.—Dr. William S. Stone read this paper. (See page 685.)

Gonorrheal Invasion of the Uterus and Fallopian Tubes.—Dr. Brooks H. Wells read this paper. He said that the subject chosen for discussion was one of the most wide-reaching importance and interest, and had to do with an evil that was born of the unbridled passions of man, a creature of darkness that stole the bloom and joy of life not only from the frail sister of the street, but too often also from the fairest and most carefully guarded daughter, striking her through him she had chosen and trusted as her husband and protector. He asked for how many childless homes was this evil responsible, for how many lives made sunless by the cloud of a chronic pelvic invalidism, how many marriages made failures by marital incapacity? For as many or more than from all other causes of pelvic ills combined. Twenty-five years ago gonorrhea was hardly considered as a cause of pelvic disability, of chronic invalidism, of sterility; now, we knew how widespread and serious were its ravages. It was difficult to find reliable statistical evidence of the relative frequency of gonorrheal endometritis and salpingitis, as compared with the frequency of infections of other portions of the genital tract in the female, but from his own experience he believed that at least one case in four developed a gonorrheal endometritis, and one in eight or ten had gonorrheal infection of the tubes. Although he had seen many cases of gonorrhea in little girls (infancy to six or eight years of age) he knew of none in which it could be shown that the disease had invaded the infantile endometrium or tubes. At or about puberty, however, with the development of these parts, the conditions were changed. Gonorrheal endometritis might be primary, but was more often secondary to infections of the lower portions of the genital tract. The only positive means of diagnosis was the microscope. It usually began within two or three months after the primary infection and sometimes within a few days. The symptoms were intensified just before, during and after menstruation, at which time the

gonococci became more numerous and virulent. Gonorrheal salpingitis was caused by an extension of infection from the uterus, and the interval between the primary infection and the invasion of the tubes might be only a few days, or might be after a long time and after periods of symptomatic health. A gonorrheal salpingitis was usually bilateral and might exist for some time without showing any distinctive symptoms. More often the symptoms were fairly well marked and rarely they might be so virulently intense as to produce a picture of acute peritoneal shock. The invasion was apt to be marked by a slight chill followed by a moderate rise in temperature, together with more or less malaise and prostration. There was pain in the ovarian regions, most often to the left side. The pain was at first sharp, cutting or pulsating, and was followed later by a dull steady ache or severe paroxysmal pain, sometimes both. The pain, when severe, was apt to radiate along the sacral plexus or sciatic nerve. The symptoms were aggravated by defecation, exertion, or coitus. Menstruation was usually profuse, irregular, and painful as a result of the accompanying endometritis and the disturbance of the pelvic circulation by the disease process. Micturition was frequent and painful. The general health suffered from the absorption of toxins and the effect of pain and anxiety. The patient often became more or less of a neurasthenic invalid. A bimanual examination revealed the enlarged tubes behind or at the side of the uterus and gave the familiar picture of a periuterine inflammation. There was sometimes a symptomatic cure, but more often the improvement was only temporary and the patient suffered recurrence of the trouble. The cases of rupture of the tubal abscess and discharge through some hollow viscus were very rare and he had never seen one. In the mild cases sterility was the most important result; in the more severe an increasing invalidism; in the rare fulminating type death might occur within a few days.

Abortive Treatment of Gonorrhea in Women.—Dr. Frederic Bierhoff outlined the following method of treatment: He said that by abortive treatment we meant that which brought about a cure upon one or two applications. The term was used in contradistinction to prophylactic or preventive methods. If women early in the course of a gonorrheal infection became aware thereof, and would go to the doctor, an abortive treatment might be possible in a fairly large number of cases. Unfortunately in almost all of the cases of gonorrhea in females, the patient presented herself for treatment when the process had already gotten a deeper foothold in the urethra, or when the urethral crypts, or the cervix uteri, had become infected. Then, of course, an "abortive cure" was impossible. In order to make the positive diagnosis of a gonorrhea early a microscopic examination of the urethral, vaginal, and cervical secretions was a *sine qua non*. If the cervix uteri was infected an abortive cure was impossible. Similarly with the Bartholinian glands, or periurethral crypts. If the diagnosis could be made early, before the gonococci had had a chance to penetrate deeply into the mucous membrane, or before the occurrence of complications, as mentioned above, and when the urethra alone, or the vulva, or vagina, or a combination of these, was the seat of infection was an abortive cure possible? When the conditions were favorable he employed the following procedure: 1. Microscopic examination of the urethral secretion or scraping, and of the vulvar secretion. 2. Cleansing of the meatus, and irrigation of the urethra and surroundings with a solution of one-fourth to one-half per cent. of soluble silver. The hand syringe or irrigator was employed and no forcible pressure was applied. In all about 300 c.c. was used for this purpose and some of the fluid was injected through the urethra into the bladder, to be there expelled by the patient. 3. Cleansing of the vulva by a stream from the irrigator. 4. A vaginal scraping was now made and examined. 5. The nozzle of the syringe was gently inserted into the vagina, so that the body of the syringe blocked the outlet. The vagina was then distended under gentle pressure, with the solution, and this was then allowed to flow out. About 300 c.c. were used. 6. A sterilized speculum was inserted into the vagina and all secretion gently wiped off, and the cervical orifice cleansed. 7. A microscopical examination of the cervical secretion was made. Should it be free from gonococci, then the vagina was lightly tamponed with absorbent gauze, saturated with five per cent. soluble silver solution, and the speculum withdrawn. He employed the tamponade whether the vagina was infected or not. 8. A urethral bougie of five per cent. soluble silver in cocoa butter was inserted into the urethra. 9. A pad moistened with one per cent. soluble silver solution was placed over the urethral and vulvar orifices and kept moist with the solution. 10. Rest in bed, if possible, bland diet, and a daily warm sitz bath completed the treatment. The patient must be subjected to the same tests as the male patient before being pronounced cured.

General Treatment of Gonorrhea in Women.—Dr. H. J. Boldt read a paper on this topic. He said that, so far as treatment was concerned, it was essential to bear in mind that in the greater majority of acute cases the disease was limited to the lower part of the urogenital tract and that, if we could bring the patients under proper care early enough, we could almost always hold the disease in check so that the upper parts of the genital tract would not be infected. The opinions as to treatment were as divergent as in the case of diphtheria before the discovery of the diphtheritic serum of Behring. Each method of treatment had its advocates and likewise its opponents. Most authors were, however, unanimous in stating that no active treatment should be employed during the acute stage. Cleanliness, restricted diet, and rest were most approved of in this stage. When the acute stage had subsided, local treatment was begun; but in the employment of local treatment, the use of vaginal douches was generally discarded. The secretion should be wiped out dry with absorbent cotton. The most favored remedy for local applications was a five per cent. solution of soluble silver. If the ducts of Bartholin were involved they must be treated on surgical principles. If a cyst formed it should be exsected. If an abscess formed it should be opened by a long incision parallel to the inner lip of the labium. The cavity after being cleansed might be swabbed with pure carbolic acid, which should immediately be wiped out again with pure alcohol. The cavity should then be packed with iodoform gauze. Where the infection remained obstinate in the small ducts he split them and used the actual cautery. Condylomata were best removed with a cautery knife. Personal observations in the matter of the various silver solutions seemed to show that it took about the same length of time to effect a cure, no matter which one was used. Some patients were cured in from four to six weeks and others were not entirely cured after six months' treatment. Patients with subacute infection did much better if they could keep themselves free from physical exertion. It was important to see that the husband was put under the care of some one who appreciated the danger of reinfection, so that cohabitation was not permitted until both husband and wife were cured. While for a time the gonococci infection might remain limited to the cervical mucosa, it must be admitted that it was extremely difficult to tell some patients when the invasion had encroached into the uterine cavity he had, therefore, placed himself on the side of those who at once attacked the entire uterine mucosa. If the patient permitted it he put her under an anesthetic and disinfected the genital tract, and then before proceeding to dilate the cervical canal the uterus was copiously irrigated with a double current bladder catheter; then the cervix was dilated slowly and gently, but effectually, and a thorough curettage was done with a sharp curette. He preferred a Martin curette for the first general abrasion of the mucosa, followed by

a small sharp curette used around the tubal openings. The uterus was then again copiously irrigated with plain sterile water, or a mild antiseptic solution, and was tamponed with a long strip of gauze soaked in a five per cent. solution of soluble silver. The rest of the genital tract was tamponed with iodoform gauze and the patient put to bed. If urethritis was still present it should be treated at this time, and also the ducts if infected. The gauze was removed on the following day, and on the third day the entire treatment, with the exception of the curettage, was repeated. If consent to curettage was not given office treatment was used. An intrauterine application was made by means of the intrauterine applicator syringe. The intrauterine tampon was left in the uterus for two or three hours and the patient directed to remove it by means of the attached string. A medicated tampon was placed in the upper part of the vagina, if desirable, and was held in place by a plain non-absorbent wool tampon. The strings of the tampon were so marked that the patient could know which to remove first. After removal of the tampons a copious antiseptic douche was used by the patient. This treatment was not as desirable as the first, as it was fraught with more risk of causing subsequent pelvic inflammation. The treatment should be repeated every two or three days, and the advantage of a perfectly made intrauterine applicator could not be overestimated. In case menorrhagia complicated gonorrheal endometritis, he had found patients benefited by the internal administration of hydrochloride of cotarnine, in doses of three grains, given in gelatin capsules, three times daily, if the previously instituted treatment did not have the desired effect. Alone, without local treatment, especially curetting, it gave unsatisfactory results. In that class of patients in whom metrorrhagia and menorrhagia were almost uncontrollable, he awaited a non-bleeding period and then made intrauterine applications of pure carbolic acid, leaving the intrauterine tampon *in situ* for a couple of hours. The treatment was repeated every second day until six or eight treatments had been applied, and at the next menstruation interval it should be repeated. He had no untoward results from the application of pure carbolic acid to the uterine cavity. In acute gonorrheal infections of the adnexa, with or without invasion of the pelvic peritoneum, rest, the application of the ice coil, or ice bags, a narcotic, preferably in the form of suppositories for the purpose of lessening peristalsis, and the avoidance of subsequent local examinations should be insisted on until the acute symptoms had subsided, when one might begin with warm vaginal douches containing a mild antiseptic. The cold applications should be continued until the temperature was normal and the patient free from pain. The patient should not leave her bed until the temperature had remained normal for one week, and upon any exacerbation of symptoms the rest treatment should be resumed. If at any time the Fallopian tubes became distended with pus, and sunk to the floor of the pelvis, further delay with conservative treatment should not be practised. The patient should be anesthetized and the cul-de-sac of Douglas widely opened. The tubes could then be incised and evacuated. There was a class of patients who, while they made a temporary recovery, had more or less pain either constantly or at varying intervals, with menstrual irregularities and perhaps occasionally acute exacerbations. Bimanual examination revealed the symptoms of salpingo-oophoritis with a metroendometritis. The Fallopian tubes were more or less distended and sometimes the adnexa and uterus were matted together in the perimetric exudate. It might be impossible in these cases to demonstrate the presence of gonococci. In these cases local treatment had proved useless in his experience. Surgical intervention was the only form of treatment that held out hope. There was another class of patients in whom the disease had, to a large extent, became spontaneously cured, so far as pyosalpinges were concerned, but the residue of the old chronic pelvic inflammation, consisting of tubes thickened and adherent, ovaries in a constant state of inflammation, and uterus perhaps smaller than normal; in some cases larger. Menstruation with this class of patients was likely to be at longer intervals, six weeks to three months, though in some instances it might be frequent, at intervals of two or three weeks, and the amount of blood lost variable. Severe dysmenorrhea might be present. Local therapy seldom benefited this class of women, who usually had been sterile or had but one child. If their suffering made it difficult for them to pursue their vocation, and they were past the middle thirties, a radical vaginal operation was most expedient. If younger, then a salpingectomy should be resorted to.

Dr. James N. West said, speaking on the treatment, that there was the greatest field of usefulness in prophylaxis. The disease which had produced such ravages on mankind was so little under control and the reason was, he believed, because it was accepted as a social evil among all, and all feared to speak of it in good society. At the Post-Graduate Hospital they had adopted active measures, measures which were practical, and which instructed people in regard to the nature of the disease, gonorrhea as well as syphilis. Also, the Society for Moral Prophylaxis in this city was discussing this question, agitating it, and bringing it before the public mind, by which the public had their eyes opened to the ravages of this disease. At the Post-Graduate Hospital a slip of paper was given to every patient suffering from either gonorrhea or syphilis, having on it printed instructions, given in simple language. They were fundamental instructions, and they went to the root of the matter. Dr. West hoped that those who were connected with clinics, and those in private practice as well, would have something of this sort to present to every patient suffering from gonorrhea or syphilis.

Dr. Lapowski discussed the papers.

Dr. Wells and Dr. Boldt closed the discussion.

Gonorrhea During Pregnancy.—Dr. J. Clifton Edgar read this paper. (See page 687.)

NEW YORK PSYCHIATRICAL SOCIETY.

Stated Meeting, Held March 6, 1907.

Dr. Allan McLane Hamilton in the Chair.

The Psychogenetic Factors in Some Paranoic Conditions, with Suggestions for Prophylaxis and Treatment.—Dr. August Hoch read this, the paper of the evening. He pointed out that among the paranoic states there were cases, and that they probably represented a large proportion, in which the psychogenesis could be clearly traced when the facts of the cases were really accessible. The theory of the development of paranoic states Dr. Hoch summarized briefly as follows, stating that besides basing his ideas upon facts of his own studies he had been influenced by the work of Adolf Meyer, Freund, Bleuler, and Jung: Every person has certain points on which he is especially sensitive. He has ideas or complexes of ideas which are associated with very strong feelings. These complexes refer either to personal defects, shortcomings, limitations, or to feelings of guilt, remorse, shame; on the other hand, to certain longings and desires. We may, therefore, generally speaking, say that they belong either to the realm of self-assertion or to the sexual sphere, in the broadest sense of the term. Now, most people are able to get square with such things, partly because their nature is such that these feelings never reach anything like a great intensity, or partly also because they have a healthy way of dealing with these matters. Other people do *not* get square with such difficulties. They do not acquire balancing, healthy habits, such as a healthy turning away from one's difficulties to outside interests, or a habit of unburdening or a certain aggressiveness and the like. While, then, such undercurrents, as we may call these complexes, when they are of any intensity have them-

selves a tendency to set narrower and narrower limits to the interest and to create a certain fascination, they often become a menace to the sanity of mind, also because they are not balanced sufficiently by sound mental tendencies. In this way there develops a growing disharmony which gradually, or sometimes under the influence of acute causes, physical or mental, may suddenly lead to an unbalancing of the mind when, finally, the undercurrents break through to the surface. But the mind, even in the cases in which the undercurrents are not handled properly, makes certain miscarried attempts at readjustment. Thus, the feelings of defect and the longings do not come to the surface as such, but are transformed; the former give rise to a general suspiciousness and delusions of persecution, probably for the same reason that we are inclined to blame everyone else except ourselves when anything which we do goes wrong; the latter give rise to ideas that the innermost longings are fulfilled. And there are still other forms of such miscarried adjustments. We see, then, that we have two things, the undercurrents and the abnormal manner of dealing with these undercurrents, upon which we should lay stress as important in the causation of these paranoic states. To a certain extent this division is, of course, artificial and the two principles often enough overlap greatly. Then again it is often difficult to find a correct or a definite formula for that which we have called abnormal mental habits, or difficult to pick out from among the complex fabric of mental reactions those which are disastrous, to estimate the dangers of certain combinations, or to correctly gauge the value of saving traits. Naturally it will often be a combination of traits rather than single traits which we have to consider, and while we speak of some reactions as dangerous mental habits they may exist in certain combinations in which they are sufficiently safeguarded. It is also very evident that causes other than an unhealthy manner of dealing with the undercurrents may enter into the causal constellation as well—such as influences which increase the strength of the undercurrents, or influences which, in other ways than those indicated, lessen the resistance, such as the action of alcohol, the menopause, and the like. These principles were demonstrated by means of careful analysis of four cases and certain indications for treatment were discussed.

Dr. H. R. Stedman of Boston, in discussing the paper, was inclined to lay more stress on the influence of heredity in affecting the progress of a genuine paranoia than did Dr. Hoch. Numbers of cases of the disorder were seen in patients who had been sensibly brought up and who were treated affectionately by their families, nothing being left undone to make their surroundings congenial and their lives smooth and happy, yet in spite of it all they developed paranoia. Little could be hoped for, he believed, in the way of materially modifying the psychogenetic factors so as to make any real impression on these cases of typical paranoia, a disease arising on a defective constitutional basis and gradually and logically developing into an inflexible system of delusional thought and conduct. He thought, however, that after the disease had developed, when family, friends, and a normal development had proved powerless to influence the disease, and the patient was sent to the hospital, his condition was more susceptible of improvement than is generally thought to be possible. He had not infrequently found the paranoiac to be rendered decidedly more manageable and his life made far more comfortable by regular friendly and explanatory talks, answering his questions, making the endeavor to set him right, and satisfying such of his minor demands as were not wholly unreasonable. The fact that many of them are hopeless and cannot be reached at all by such means—in fact, only become worse in consequence—accounted, he thought, for the tendency that exists to pay them as a class little or no systematic attention such as Dr. Hoch adopts with his cases. Dr. Stedman questioned if the reader had not chiefly in mind the paranoid state rather than the paranoiac, that symptomatic, persecutory condition so often found in dementia præcox. If so, he was wholly in accord with his view that much might be done in the way of prophylaxis. Dr. Hoch's masterly analysis of the psychogenetic conditions in his cases showed this plainly and he believed it to be due to the fact that the morbid direction of their thought had become less impaired than in the true paranoiac. Dr. Stedman felt the same confidence that he had expressed at length several years ago, that not a few cases of this kind, when recognized early by the psychiatrist while yet the patient is comparatively comfortable may be saved from an attack by well directed medical oversight and guidance and regulation of his habits and sourroundings. He attached little importance to the menopause as a special causative factor in insanity, as individual experience and statistics seem to show quite conclusively that paranoia develops to the same extent in both sexes during the period of life in which the menopause occurs.

Dr. Charles L. Dana said that he had been interested in Dr. Hoch's analysis, which was instructive as showing that in a certain group of cases of paranoia conditions might be improved by careful therapeutic effort. He had not been in a position to carry out this method of treatment, which could not be very successfully employed by those not connected with institutions. He agreed with Dr. Stedman as to the importance of hereditary taint in all these cases, and that a goodly proportion of paranoiacs develop in spite of careful bringing up. Few of these patients could be influenced unless they were taken in hand very early. He had been much interested in two or three cases of paranoia which illustrated that the undercurrent does not always break through in a way that particularly disturbs the mental makeup or general life of the patient. Such a case was a woman, about fifty years of age, now under his care, who was first seen by him when she was forty years old. She was married and the mother of two healthy children. About fifteen years before he first saw her she had developed delusions of a certain kind of persecution—that when she went out on the streets people made remarks about her, trying to annoy her and to injure her. She had these delusions throughout her married life and during her pregnancies. She was a good mother, however, and to most people who knew her she remained a good, kindly woman, about whose mental condition no one had suspicions except her husband, some members of her family, and Dr. Dana. She was probably preserved from a general paranoiac state by the fact that she was able to stay in the house and keep away from sources of irritation. He had had under observation also a man, now forty years old, who had been engaged in business all his life. For fifteen or twenty years this patient had had similar delusions of persecution—that the police and detectives were after him and that attempts were being made to watch him. But this undercurrent delusion never broke through except in one little spot in his brain. One or two of his children developed dementia præcox at the age of sixteen. Such very limited types of paranoia certainly lent themselves to treatment by instruction and by careful selection of environment, which was all essential. As to the general correctness of Dr. Hoch's analysis there could be no question.

Dr. Maurice C. Ashley of Middletown, N. Y., agreed with Dr. Hoch in the main, but he questioned whether the therapeutic talks with paranoiacs would accomplish very much as a curative measure. In his experience there had been no such beneficial results. He recalled one paranoiac who, for ten years, had believed that he had been giving him poison. At first the patient was inclined to retaliate; he threatened, and made definite efforts to take the life of the doctor's children. The man had some

somatic symptoms which he himself attributed to the poison which he thought had been given him. He still has the delusions, but no longer attempts to execute his threats. Another patient, a woman, for eight years had believed that he had been turning an electric current upon her for the purpose of annoying her. Every argument had been used to convince her that this was impossible, but without effect. As the disease progresses the reason of such patients becomes enfeebled and less active, and while they continue to have their delusions they become accustomed to them and cease to react much to them.

Dr. William Hirsch thought that in forming a definite opinion concerning the cases analyzed by Dr. Hoch, it must first be determined whether one had to deal with genuine paranoia, or with a paranoical state of another disease. Genuine paranoia is always a congenital and not an acquired disease, although the true paranoical symptoms often do not manifest themselves during the earlier part of life. But there is always a congenital condition, a constellation of mental factors, which not only predisposes to, but which necessarily develops, at some time of life, such a combination as to produce that mental condition known as paranoia. When such a point in any given case would be reached cannot be determined in advance, but we are, in most cases, able to predict the development of a true paranoia. Various conditions, such as environment, worry, etc., might have something to do with it, at least with a premature manifestation of the condition. He did not believe, however, that in any given case anything could be done to prevent the manifestation of the paranoical condition, even though it were recognized that the development of such a condition existed. This opinion was not based merely on theory. In his practice he had had children brought to him whose parents realized that they were a little peculiar, nothing more, but whom he recognized as abnormal individuals who in later life would become paranoiacs. In such of these cases as he had been able to follow for ten or fifteen years he had found that they developed genuine paranoia in spite of all the precautions which had been taken. He had warned the mother not to let the child have any impressions which would stimulate the imagination or fancy of the child, not to let it read any fiction, to guard it against any undue emotions; all this was carried out with the greatest care. But at some time in life, generally after an unusual emotion, such as falling in love, slight business troubles—something which otherwise would be of no importance—would develop a true paranoia. A normal individual, normal from the start, would never develop paranoia. A normal individual might develop melancholia, or some other acute disease, but never paranoia. When he said one must differentiate between types he meant cases in which there was genuine paranoia and those in which there was a paranoical state. The paranoical state might occur in a great many psychoses. He had seen such a case lately. A man of sixty years of age, a good business man, perfectly normal all his life, suddenly developed a paranoical condition; he had delusions and hallucinations, imagined there was a conspiracy against him, that his neighbors tried to kill him, etc. After remaining in this condition for nine months he gradually became demented. He is still living, and is suffering from a condition of general arteriosclerosis. The case could be defined as dementia senilis, but not as paranoia.

Dr. P. C. Knapp of Boston thought it a mistake always to regard delusions of persecution, with hallucinations of one form or another, as constituting paranoia, and that we should be guarded in speaking of such conditions as paranoiac states. He agreed entirely with Dr. Hirsch's opinion that true paranoia, while not a congenital condition, is dependent upon a congenital malarrangement, so to speak, of the brain. Tanzi had taken the same position, viz., that, whereas other forms of mental disease might be spoken of as true diseases, paranoia was not a disease, but a morbid congenital state which, later in life, under the influence of various factors, might develop into typical paranoia with hallucinations and delusions. He thought that the "undercurrent" did not always "break through." In this connection he cited the case of a woman who, for years had had a limited type of delusion. She had lived a secluded, narrow life in one of the smaller New England cities; for many years she had been active in the care of her household and family and in church work; she had been trained in the old New England habit of keen theological discussion and argument, and for many years she had had the very definite idea that she had been excommunicated from the church. In the main the idea had been suppressed, many of her church associates did not know of it, and those who did kept it secret. The idea existed for many years without going on to any real mental disturbance. Cases were not uncommon in which the delusions occupied a limited field in the consciousness and affected but little the conduct. With a true paranoiac, however, he questioned very much the real importance of any emotional stress, or of any psychical ideas as influencing materially the genesis of the disorder. They might influence the development in so far as changes in modern belief influence the character of delusions. As Dr. Hirsch had suggested, it was impossible to protect these patients from all influences that might give rise to the condition. Not infrequently delusions of persecution developed in normal individuals in connection with hallucinatory conditions having a distinctly physical basis. He had recently seen such a case, a man with well systematized delusions on an alcoholic basis, derived largely from tactile disturbances, which proved to arise from the paresthesias of a very mild alcoholic neuritis.

Dr. Pierce Clark was of the opinion that the cases cited by Dr. Hoch might be called paranoid states rather than typical or true paranoia. The therapeutic suggestions outlined would be of undoubted value in these paranoid states. During the past three years he had been treating several cases by analyses and talks, and the method had been very advantageous. He thought the method was of little use in true paranoia, as the mental state was too fixed; his experience in asylum service had proved this fact to his entire satisfaction.

Dr. Swepson J. Brooks of Harrison, N. Y., was very glad to know of the success Dr. Hoch had had with therapeutic talks. He had tried this plan and found it productive of results in many cases, but the patients would relapse into the old condition after being released from institutions. He presumed that Dr. Hoch had reference in his paper to simple paranoid states. The question of paranoia was a hard one to go into, and sometimes one almost concluded that paranoia and paranoid states were the same, only differing in degree. The forcing of patients to do things, as suggested by Dr. Hoch, was often neglected. He had in mind two cases in which it certainly had a very salutary effect. One case was a woman, forty-five years of age, who had delusions of persecution. She was put in a very quiet hall. She complained that she was merely brought to the place to be put in jail, that there were no sick people there, and that she would like to see some sick people. She was allowed to see some sick patients; the next morning she was convinced, and she got well. That was four years ago and she had remained well since. The other case was of the manic-depressive type. The patient confessed after her recovery that her family physician had had to force her to take medicine, that he would stand her up against the wall and knock her head against it if she did not take the medicine, and that she believed his method did good.

Dr. Smith Ely Jelliffe said that Dr. Hoch's paper had offered glimpses into a large and but partly explored territory. To him, four different trends of thought were

suggested, all of which were the subjects of much investigation. In the first place, the importance of the study of the mental development of the child was emphasized. The work of Weygandt, on Abnormal Children; of Koch, on Pathological Inferiority; of Hall, in his masterly work on Adolescence; and of Sommer, on Character and Personality, were instances in point as to the activity of these lines of investigation. As to the psychogenic origin of certain types of delusions, Dr. Jelliffe was in accord with Dr. Hoch. He spoke of the help that might come from the literary side, as evidenced by the stories of Henry James, "The Turning of the Screw," and "The Two Magics"; Weir Mitchell's "Constance Trescott," and Ansty's "Statement of Stella Maberly." In all these this type of delusion formation is beautifully brought out, with great literary charm, if not with scientific pedantry. Therapeutically, he deemed Dr. Hoch's paper as stimulating, and he himself regarded certain phases of the subject with optimism. Paranoia, he said, was too large a term to use in a general blanket manner. While it is true that little can be accomplished by the most tactful of psychotherapeutic conversations in chronic lunatics who have been in the asylums for years, yet the important factor in the whole problem is to recognize the beginning stages, before the delusional ideas have become too firmly crystallized. Greater success had not been attained because the psychogenic origin of many delusional states had not been sufficiently understood. It required a rare tact to work on these patients, and the outlines given by Dubois, Dejerine, and Oppenheim were but the beginnings of a scientific psychotherapy which for some time had been grasped at by pseudoscientists. Dr. Jelliffe desired to rank himself with those who saw a hopeful outlook for the amelioration, if not cure, of certain cases of dementia præcox, and of the paranoid states, by early and intelligent psychotherapy.

Dr. George H. Kirby had been interested of late in the management of paranoic states along the lines suggested by Dr. Hoch, and thought that much could be accomplished in this way toward the correction of morbid trends. Dr. Hoch's work was particularly important in regard to the study of delusions in general. Such a method of analysis opened the way to an understanding of certain mechanisms which heretofore had been practically inaccessible.

Dr. Hoch, in closing the discussion, stated once more that what he wished to bring out was the fact that certain paranoiac states were produced by purely mental causes, *i.e.* by conflicts and unhygienic ways of dealing with them, and that they were more or less amenable to treatment early in the course, but that naturally he did not mean to claim that old cases of paranoia could thus be influenced. It was necessary in order to help such cases that one could still get at the root of things and explain to the patient the genesis of his delusions and train him to healthy mental habits. The criticism that his cases were not cases of typical paranoia, he could not quite understand, because he was unable to see where the line could be drawn between cases such as his and cases of so called typical paranoia. Again, to say that paranoia was caused by heredity was an exceedingly unsatisfactory way of stating the situation because it did not mean enough. He had claimed that some paranoiac states were due to an unhealthy dealing with conflicts. Such an unhealthy dealing may be due to tendencies which were more or less inherited, but that it was time to make an attempt at determining what these tendencies were, because the mere statement of heredity was absolutely barren, that the same may be said about the statement which had been made that paranoia was due to a congenital malarrangement. If Dr. Hirsch said that a normal individual would not develop paranoia, this was doubtless true, if by normal individual was meant one who had perfectly healthy mental habits.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS

Oklahoma Territorial Medical Examining Board.

December 20, 1906.

ANATOMY.

1. Describe the femur, its articulations and what portions of it are not covered by periosteum.
2. Give the number of sutures and fontanelles in the skull, and by what and how is each formed?
3. Where is the reticular elastic cartilage found, and locate the coracoid and acromion process.
4. Give origin, insertion and uses of the following muscles: trapezius, supinator-longus, latissimus-dorsi, internal-oblique and the gracilis.
5. Describe the right ventricle of the heart, give its capacity and name the valves connected with the ventricle.
6 and 7. Locate and give uses of the Fallopian and Eustachian tubes, lacrymal duct, prostate gland, crystalline lens, antrum of Highmore, clitoris, spleen, ureter, suprarenal capsule, the abdominal and thoracic cavities.
8. Give origin and branches of inferior dental and the mastoid arteries.
9. Name the bones, main muscles, arteries, nerves, and other fascia gone through in amputating leg at the thigh.
10. Enumerate the changes the bones of the lower jaw undergo in very aged persons.

PHYSIOLOGY.

1. Define special and comparative physiology.
2. Name the digestive juices and the organs that produce them, and give their actions on bread, eggs, milk, and butter.
3. Name the ferments found in the digestive juices and give source of glycogen and dextrose.
4. Give the composition of normal and healthy urine, and of urine in a case of diabetes mellitus.
5. Give structure and functions of the liver and kidneys.
6. Where and how is urea formed, and give cause of rigor mortis.
7. How do the products of digestion find their way into the blood?
8. What would be the results of eating in excess of albuminous, oleaginous, and farinaceous foods.
9. Give the changes of the air in respiration and the respiratory changes in the blood.
10. Name the heat-producing tissues of the body.

CHEMISTRY AND URANALYSIS.

1. Define (a) chemistry, (b) matter, (c) atom, (d) molecule, (e) element.
2. Differentiate between chemical and physical changes in matter and illustrate.
3. Define chemism, atomic weight, specific gravity.
4. Name the alkaline elements; give symbols for the gaseous elements.
5. Name two *ic* and two *ous* salts of mercury and give formula.
6. Give common name, formula, and uses of four zinc salts.
7. Give common names of following formula, CO_2, H_2O_2, $FeSO_4$, NACl, $HgCl_2$.
8. Give chemical name and formula of borax, marble, blue vitriol, Rochelle salts, oil of vitriol.
9. Discuss arsenic, mention its properties, compounds, and uses.
10. Name four normal, and give in detail tests for four abnormal constituents of urine.

MATERIA MEDICA AND THERAPEUTICS

1. Give therapeutics of quinine, iron, strychnine, digitalis
2. Give dosage of remedies you use in pneumonia, membranous croup, typhoid fever.

It is proposed in this department to publish from time to time the examination papers of the various State Boards, in order that a candidate may become familiar with the character of the examination and so in some measure free himself in advance from the nervousness and dread which the unknown inspires. In furtherance of the same object answers to some of the questions will be published in order to show the candidate what the examiners expect of him. Not all the questions of all the papers will be so treated, for the answers to many, especially in the anatomical papers, are obvious or can be found in the index of any text-book on the subject; the answers to other questions, especially in the surgical papers, must sometimes be omitted because of the space they would demand. The candidate for a medical license will not find in these answers a short and easy road to success in the examination, for he is not likely to meet the same questions in the papers placed before him by the examiners. The object of publishing the questions and answers is only, as noted above, to acquaint the candidate with the general character of these examinations and to inspire him with confidence in the result of his trial.

3. Give dosage and indications for four remedies you use in jaundice, rheumatism, malarial fever.
4. Give habitat, preparation, dosage, and uses of twelve leading remedies you carry in your medicine case.
5. Give indications that guide you in the use of each of the remedies you mention in answer to previous question.

PHYSICAL DIAGNOSIS AND PATHOLOGY.

1. Name the topographic lines of the thorax, outline and locate the heart's area of absolute dullness and the upper border of the normal liver.
2. Describe the usual course of parenchymatous nephritis, also interstitial nephritis. In what class of patients is the latter most frequently observed? How would you differentiate one from the other?
3. Under what conditions would occur a physiological leucocytosis? Under what pathological conditions would you expect to find a polymorphonuclear leucocytosis? A lymphocytosis?
4. Designate which component part of the spinal cord is involved in locomotor ataxia and describe the metamorphosis of structure characterizing the pathological process.
5. What pathological changes occur in cirrhosis of the liver?
6. Give differential diagnosis between septicemia and pyemia.
7. Give the principal diagnostic points of difference between mitral regurgitation and aortic regurgitation.
8. Give differential diagnosis between scarlet fever and erysipelas in their early stages.
9. Give differential diagnosis between phlebitis and lymphangitis.
10. Give differential diagnosis between variola and varicella.

PRACTICE OF MEDICINE.

1. What are the intrinsic and extrinsic causes of dilatation of the heart with broken compensation? How would you treat the latter condition when very extreme?
2. Describe Bell's paralysis, Cheyne-Stokes respiration.
3. What are the early manifestations of pulmonary tuberculosis and give your method of management in a case.
4. Give the etiology, pathology, symptoms, treatment, dietetic, medicinal, hygienic and prophylatic of enterocolitis.
5. Give symptoms and treatment of acute ptomaine poisoning.
6. Give symptoms and treatment of pulmonary edema.
7. Give cause, symptoms, and treatment of herpes zoster.
8. Name one infectious and one contagious disease and give diagnosis of the diseases named.
9. Describe a case of uremic coma and your treatment for same.
10. Give symptoms and diagnosis and treatment of follicular tonsillitis.

OBSTETRICS AND GYNECOLOGY.

1. Define menstruation, give duration, age of appearance and cessation, and abnormal manifestations.
2. Name and give measurements of female pelvis; of fetal head.
3. Give briefly the anatomy of uterus, ovaries, placenta.
4. Give theory of menstruation; of conception.
5. Name the three important forms of hemorrhage met with in obstetric practice and give causes and treatment of each.
6. Define ectopic gestation, caput succedaneum, vitellus, amnion.
7. Into what stages is labor divided, and where does each stage begin and end?
8. How would you treat mastitis, puerperal eclampsia?
9. Give in detail technique of repairing laceration of perineum involving floor of vagina.
10. How would you prepare your patient for delivery and yourself for attendance in a case of labor?

SURGERY.

1. Diagnose, give prognosis and treatment of the following diseases: Erysipelas, rhinitis, pyemia, and traumatic or surgical fever.
2. Describe and differentiate the following, viz.: Concussion and contusion, an incised, punctured, lacerated, gunshot and poisoned wounds.
3. Give signs of fracture, dislocation, reduction, and the process of repair.
4 and 5. Give differential diagnosis and treatment of fracture of the surgical neck, capsular fracture of the femur, and a case of hip joint disease.
6. Define and give treatment of tinea-versicolor, tinea-circinatis, herpes zoster, and scabies.
7. How would you diagnose? Give prognosis and treatment of septicemia, pyemia, and septic-pyemia.
8. Give differential diagnosis between coma the result of an injury and that produced by opium poisoning, alcoholic intoxication, apoplexy, and uremic poisoning.
9. Describe and give treatment of hydrocele, hypospadias, varicocele, hematocele, and epispadias.
10. Give symptoms, prognosis, and technique of the operation for an ectopic gestation, or an extrauterine pregnancy.

MEDICAL JURISPRUDENCE.

1. In a medicolegal sense, what constitutes a dying declaration and what is necessary to make it evidence in a court of justice, and how should it be taken?
2. Determine in a case of supposed infanticide whether the child was still-born or killed after birth.
3. What are the symptoms and treatment of corrosive sublimate poisoning?
4. At what period will a body float after being drowned?
5. In a case of opium poisoning, what are the post-mortem symptoms?
6. What is malpractice?
7. How would you treat a patient suffering from poisoning by coal gas?
8. What are the symptoms and treatment for poisoning by the castor bean and what is considered a lethal dose?
9. What are symptoms of poisoning by wood alcohol and treatment for same?
10. Give symptoms and treatment for poisoning by turpentine taken internally.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

OKLAHOMA TERRITORIAL MEDICAL EXAMINING BOARD.

December 26, 1906.

ANATOMY.

3. Reticular elastic cartilage is found in the external ear, in the Eustachian tube, in the epiglottis, in the cartilages of Santorini and of Wrisberg in the larynx.

9. *Bone*: the femur. *Main muscles*: rectus femoris, vastus externus, crureus, vastus internus, biceps, semitendinosus, semimembranosus, adductor magnus, gracilis, adductor longus, sartorius. *Arteries*: femoral, profunda femoris. *Nerves*: great sciatic, small sciatic, external cutaneous, middle cutaneous. *Fascia*: superficial fascia, fascia lata.

10. "The changes which the lower jaw undergoes after birth relate (1) to the alterations effected in the body of the bone by the first and second dentitions, the loss of teeth in the aged, and the subsquent absorption of the alveoli; (2) to the size and situation of the dental canal, and (3) to the angle at which the ramus joins with the body.

"*At birth* the bone consists of lateral halves, united by fibrous tissue. The body is a mere shell of bone, containing the sockets of the two incisor, the canine, and the two temporary molar teeth, imperfectly partitioned from one another. The dental canal is of large size, and runs near the lower border of the bone, the mental foramen opening beneath the socket of the first molar. The angle is obtuse (175 degrees), and the condyloid portion nearly in the same horizontal line with the body; the neck of the condyle is short, and bent backward. The coronoid process is of comparatively large size, and situated at right angles with the rest of the bone.

"*After birth* the two segments of the bone become joined at the symphysis, from below upward, in the first year; but a trace of separation may be visible in the beginning of the second year near the alveolar margin. The body becomes elongated in its whole length, but more especially behind the mental foramen, to provide space for the three additional teeth developed in this part. The depth of the body becomes greater, owing to increased growth of the alveolar part, to afford room for the fangs of the teeth, and by thickening of the subdental portion, which enables the jaw to withstand the powerful action of the masticatory muscles; but the alveolar portion is the deeper of the two, and, consequently, the chief part of the body lies above the oblique line. The dental canal after the second dentition is situated just above the level of the mylohyoid ridge, and the mental foramen occupies the position usual to it in the adult. The angle becomes less obtuse, owing to the separation of the jaws by the teeth. (About the fourth year it is 140 degrees.)

"*In the adult* the alveolar and basilar portions of the body are usually of equal depth. The mental foramen opens midway between the upper and lower border of the bone, and the dental canal runs nearly parallel with the mylo-

hyoid line. The ramus is almost vertical in direction, and joins the body nearly at right angles.

"*In old age* the bone becomes greatly reduced in size; for with the loss of the teeth the alveolar process is absorbed, and the basilar part of the bone alone remains; consequently, the chief part of the bone is *below* the oblique line. The dental canal, with the mental foramen opening from it, is close to the alveolar border. The rami are oblique in direction, the angle obtuse, and the neck of the condyle more or less bent backward." (Gray's *Anatomy.*)

PHYSIOLOGY.

1. *Special Physiology* treats of the nature and function of particular organs, as the lungs, heart, etc.

Comparative Physiology treats of the study and comparison of the physiology of different animals (or plants).

2. The digestive juices are: (1) Saliva, produced by the salivary glands (parotid, submaxillary and sublingual). (2) Gastric juice, produced by the stomach. (3) Pancreatic juice, produced by the pancreas. (4) Succus entericus, produced by the small intestine. (5) Bile, produced by the liver.

Bread consists of proteid, fat, and carbohydrate; *eggs* of proteid and fat; *milk* of proteid, carbohydrate, and fat; *butter* of fat, and a little proteids. They all contain water.

For the effect of the digestive juices on these constituents, see next answer.

3.—

	Ferment	Function
Saliva	Ptyalin	Changes starch into dextrin and sugar.
Gastric juice	Pepsin	Changes proteids into proteoses and peptones in an acid medium.
	A curdling ferment	Curdles the casein of milk.
Pancreatic juice	Trypsin	Changes proteids into proteoses and peptones, and afterwards decomposes them into leucin and tyrosin; in an alkaline medium.
	Amylopsin	Converts starches into maltose.
	Steapsin	Emulsifies and saponifies fats.
	A curdling ferment	Curdles the casein of milk.

Glycogen is formed in the liver, chiefly from the carbohydrates of the food, and also from the proteids.

Dextrose is derived from the digestion of starch and cane sugar.

4. The following table (from Dunglison's *Medical Dictionary*) gives the average composition of normal urine:

	(Parts in 1000.)		Voided Per Day	
			Grains	*Grams*
Water	950.00			
Urea	28.00		520.80	35.00
Uric acid	0.60	Organic	11.16	0.75
Hippuric acid	0.35	matter,	6.51	0.44
Creatinin	0.65	37.60	12.09	0.81
Extractives	8.00		148.80	10.00
Sodium chloride	8.00		148.80	10.00
Phosphoric acid	2.00		37.20	2.50
Sulphuric acid	1.25	Inorganic	23.45	1.56
Lime (CaO)	0.25	matter,	4.65	0.31
Magnesia (MgO)	0.30	12.40	5.58	0.37
Potash (K_2O) and soda, (Na_2O)	0.60		11.16	0.75
Total	1000.00		930.20	62.49

In diabetes mellitus the total quantity voided is greatly increased, the specific gravity is higher, and it contains amounts of sugar varying from an ounce to two pounds per day; the urea and uric acid are also increased.

5. The functions of the *liver* are: (1) The secretion of bile, (2) the formation of glycogen, (3) the formation of urea and uric acid, (4) the manufacture of heat, and (5) the conversion of poisonous and harmful into inert material.

The functions of the *kidney* are: (1) The secretion of urine, and (2) the secretion of an "internal secretion."

6. Urea is formed in the liver, from proteids, by a process of hydrolysis and of oxidation.

Rigor mortis is caused by the lowering of the body temperature and the coagulation of the albumin of the muscles.

7. By absorption through the portal vein and the lacteals. The portal vein absorbs the greater part of the water, salts, peptones, sugar, and soaps, and a trace of fats. The lacteals absorb the greater part of the fat, some water, and peptones, and a trace of salts and sugar.

8. "*Albuminous food* in excess promotes the arthritic diathesis, manifesting itself as gout, gravel, etc. *Oleaginous food* in excess gives rise to the bilious diathesis. *Farinaceous food*, when long continued in excess, favors the rheumatic diathesis by the development of lactic acid."—(Brubaker.)

9. The changes of the air in respiration are shown in the following table:

	Inspired Air	Expired Air
Oxygen	21 per cent.	16.0 per cent.
Nitrogen	79 per cent.	79 per cent
Carbon dioxide	0.04 per cent.	4.4 per cent.
Other gases	Rare	Often present.
Watery vapor	Variable	Saturated.
Temperature	Variable	That of body.
Volume	Varies	Diminished.
Bacteria	Always present	None
Dust	Always present	None

The respiratory changes in the blood: (1) In the *lungs*, the blood is changed in color, gains oxygen, loses carbon dioxide, loses heat, and loses watery vapor. (2) In the *capillaries of the body*, the blood loses oxygen and receives carbon dioxide.

10. The heat-producing tissues of the body are: (1) The muscles, during contraction; (2) the secreting glands, during functional activity; (3) the brain, during mental activity; (4) all the tissues of the body are capable of adding to the total amount of body heat, but the first three named are the chief contributors.

CHEMISTRY AND URANALYSIS.

1. *Chemistry* is that branch of science which treats of the composition of substances, their changes in composition, and the laws governing such changes.

Matter is that which occupies space, or is evident to one or more of the senses.

An atom is the smallest quantity of an element that can enter into chemical action.

A molecule is the smallest quantity of any substance (element or compound) that can exist in a free state.

An element is a substance which cannot by any known means be split up into two or more dissimilar substances.

2. "A bar of soft iron may be made to emit light when heated, or sound when caused to vibrate, or magnetism when under the influence of an electric current. Under the influence of these *physical forces* the iron suffers no change in composition, and, on cessation of the action of the inciting force the iron returns to its original condition. But if the iron be heated in an atmosphere of oxygen, both the iron and a part of the oxygen disappear, and a new substance, a new chemical species, is produced, having properties of its own, different from those of either the iron or the oxygen. In this case there has been *chemical action*, causing change of composition, as the new substance contains both iron and oxygen. The result of such action is, moreover, permanent, and the new product continues to exist, until modified by some new manifestation of chemical action."—Witthaus' *Manual of Chemistry.*)

3. *Chemism* is the force which holds together the atoms in a molecule.

Atomic weight is the weight of an atom of an element as compared with the weight of an atom of hydrogen.

Specific gravity is the weight of a substance compared with the weight of an equal volume of another substance taken as a standard.

4. The alkaline elements are: (1) The alkali metals: lithium, sodium, potassium, rubidium, cesium, and (2) the metals of the alkaline earths: calcium, barium, strontium.

The symbols of the gaseous elements are: H, O, F, Cl, N, He, Ne, A, Kr, and Xe.

5. Mercuric chloride, $HgCl_2$; mercuric oxide, HgO; mercurous chloride, Hg_2Cl_2; mercurous oxide, Hg_2O.

6. (1) Zinc chloride, butter of zinc, $ZnCl_2$, used as a caustic, disinfectant, antiseptic, and for embalming.

(2) Zinc sulphate, white vitriol, $ZnSO_4$, used as a styptic, astringent, and emetic.

(3) Zinc oxide, tutty, ZnO, used in the arts as a pigment.

(4) Zinc carbonate, calamine, $ZnCO_3$, used as a dusting powder and astringent.

7. CO_2, common name carbonic acid; H_2O_2, common name peroxide of hydrogen; $FeSO_4$, common name green vitriol, or copperas; NaCl, common name table salt; $HgCl_2$, common name corrosive sublimate.

8.—

	Chemical Name	Formula
Borax	Disodic tetraborate	$Na_2B_4O_7$
Marble	Calcium carbonate	$CaCO_3$
Blue vitriol	Cupric sulphate	$CuSO_4$
Rochelle salts	Potassium sodium tartrate	$KNaC_4H_4O_6$
Oil of vitriol	Sulphuric acid	H_2SO_4

9. Arsenic is an element, with atomic weight of 75, molecular weight 300, valence three or five; the molecule contains four atoms. It occurs chiefly in combination in orpiment, realgar, mispickel or iron pyrites. It is a crystalline solid or an amorphous powder, the vapor has an odor of garlic; it is insoluble in water; it unites with nascent hydrogen; it burns in oxygen; on being heated in air it is converted into arsenic trioxide, As_2O_3. It is used in the manufacture of shot, flypapers, fireworks, and pigments. Its chief compounds are: Hydrogen arsenide, arsenic trichloride, arsenic trioxide, arsenic pentoxide, arsenous acid, arsenic acid, arsenic bisulphide, arsenic trisulphide, arsenic pentasulphide.

10. Four normal constituents of urine: Water, urea, uric acid, and sodium chloride.

Test for (1) *Albumin*: The urine must be perfectly clear. If not so, it is to be filtered, and if this does not render it transparent it is to be treated with a few drops of magnesia mixture, and again filtered. The reaction is then observed. If it be acid, the urine is simply heated to near the boiling point. If the urine be neutral, or alkaline, it is rendered *faintly* acid by the addition of dilute acetic acid, and heated. If albumin be present, a coagulum is formed, varying in quantity from a faint cloudiness to entire solidification, according to the quantity of albumin present. The coagulum is not redissolved upon the addition of HNO_3.

Test for (2) *Sugar*: Render the urine strongly alkaline by addition of Na_2CO_3. Divide about 6 cc. of the alkaline liquid in two test tubes. To one test tube add a very minute quantity of powdered subnitrate of bismuth, to the other as much powdered litharge. Boil the contents of both tubes. The presence of glucose is indicated by a dark or black color of the bismuth powder, the litharge retaining its natural color.

Test for (3) *Acetone*: Add a few drops of a freshly prepared solution of sodium nitroprussid, and then KHO or NaHO solution, when, in the presence of acetone, the liquid is colored ruby red, and on supersaturation with acetic acid changes to purple.

Test for (4) *Indican*: The urine is mixed with one-fifth its volume of 20 per cent. solution of lead acetate and filtered. The filtrate is mixed with an equal volume of fuming hydrochloric acid containing 3:1000 of ferric chlorid, a few drops of chloroform are added, and the mixture strongly shaken one to two minutes. With normal urine the chloroform remains colorless, or almost so; but if an excess of indoxyl compounds be present the chloroform is colored blue, and the depth of the color is a rough indication of the degree of the excess.

—(From Witthaus' *Essentials of Chemistry.*)

PHYSICAL DIAGNOSIS AND PATHOLOGY.

1. The topographic lines of the thorax are *vertical lines* and *horizontal lines*, as follows:

"The *vertical lines* are from front to back: (1) The *midsternal line* and its prolongation upward. (2) The *sternal line*, corresponding to the lateral border of the sternum. (3) The *parasternal line*, midway between (2), and (4) The *mamillary or nipple line*, which, even in the male thorax, does not always pass through the nipple, but may be more exactly defined as a vertical line dropped from the center of the clavicle. (5) The *anterior axillary line*, drawn through the point at which the great pectoral muscle cleaves the chest when the arm is raised sidewise to a horizontal line. (6) The *middle axillary line*, drawn through midway between (5) and (7) The *posterior axillary line*, which is drawn through the point at which the latissimus dorsi leaves the chest, the arm being raised as in (5). (8) The *scapular line*, drawn through the inferior angle of the scapula. (9) The *midspinal line*.

"The *horizontal lines* are, in front and at the side, from above downward: (1) A line running from the cricoid cartilage to the outer end of the clavicle. (2) The line of the clavicles. (3) A line through the third chondrosternal articulation. (4) A line through the sixth chondrosternal articulation. Posteriorly they are (5) A line through the spines of the scapulæ. (6) A line through the inferior angles of the scapulæ. (7) A line through the spine of the twelfth dorsal vertebra."—(Butler's *Diagnostics of Internal Medicine.*)

3. A *physiological leucocytosis* is found: In the newborn, after parturition, after exertion, after a cold bath or massage, during pregnancy, and during digestion.

A *polymorphonuclear leucocytosis* is found in all acute inflammatory diseases, in certain of the acute infectious diseases, and accompanying the cachexia of malignant disease.

A *lymphocytosis* is found in lymphatic leukemia, and sometimes in sarcoma, and whooping cough.

4. In locomotor ataxia the posterior columns of the spinal cord and the posterior nerve roots are involved.

The process is destructive and progressive; it is not a simple wasting, although the nerve fibers are atrophied, but it is characterized by irritation, changes in the axis cylinders, overgrowth of the connective tissue, and sometimes congestion. The spinal ganglia may be affected; the membranes over the affected parts are adherent and opaque.

6. *Septicemia* begins with a rigor, followed by a rise of temperature up to about 104° F., which remains constant. The pulse is weak and progressively rapid; there is anorexia and constipation, which is followed by diarrhea; the urine contains albumin; the temperature may become subnormal. There are no repeated rigors and no secondary (metastatic) abscesses.

Pyemia begins with a rigor, which may last for half an hour, and is repeated every one or two days. The temperature rises as in septicemia, but rapidly falls, and at the same time the patient suffers a profuse perspiration. The pulse is weak and rapid; there is anorexia; and there may be delirium, with jaundice and signs of abscesses in the lungs, joints, etc. In pyemia there are repeated rigors and secondary abscesses.

7. In *mitral regurgitation* there is a systolic murmur, heard loudest at the apex, transmitted toward the left axilla, and often heard at the angle of the left scapula. The heart is enlarged.

In *aortic regurgitation* there is a diastolic murmur, heard loudest at the second interspace, transmitted down the sternum. The left ventricle is hypertrophied. There will also be present Corrigan's pulse, and pulsating arteries in the neck.

8. In *erysipelas* the rash is local; it is not punctate; the surface of the skin is smooth and edematous; bullæ are often present, and have a well-defined margin; the skin of the affected part is burning, tender, tense, and painful.

9. *Phlebitis* is apt to begin in a varicose vein; the vein is felt as a hard cord; edema is present, and the skin has a dusky hue.

Lymphangitis generally begins in a sore, the neighboring lymph glands are involved, it tends to spread in a spiral line, and the skin has a rosy tint, which appears before the edema.

10. (1) Very young children are attacked with varicella, whereas variola usually shows itself in adults. (2) Vaccinated children readily take varicella; not so variola, even in the modified form. (3) Children who have had varicella may contract variola, even soon afterwards; or the two diseases may co-exist. (4) Varicella is non-inoculable, whereas variola is notoriously so. (5) The eruption of varicella appears in twenty-four hours; that of variola not till the third day. (6) The febrile symptoms continue after the eruption appears in varicella; those of variola subside. (7) In varicella the spots come out in successive crops; this is never seen in variola. (8) The spots in varicella are unilocular, and collapse on being punctured; the spots in variola are multilocular, and do not collapse on being punctured. (9) In varicella the eruption is very irregular, and appears over the body generally; in variola it appears in groups of threes and fives, and is always seen on the limbs. (10) The papule in varicella is soft, and disappears on stretching the skin; in variola it is hard and shotty, and does not disappear on stretching the skin. (From J. W. Moore's work on *Variola and Varicella.*)

PRACTICE OF MEDICINE.

2. In *Bell's paralysis* "the muscles of the face being all powerless, the countenance acquires on the paralyzed side a characteristic, vacant look, from the absence of all expression; the angle of the mouth is lower, and the paralyzed half of the mouth looks longer than that on the other side; the eye has an unmeaning stare, owing to the paralysis of the orbicularis palpebrarum. All these peculiarities increase the longer the paralysis lasts, and their appearance is exaggerated when at any time the muscles of the opposite side of the face are made active in any expression, or in any of their ordinary functions. In an attempt to blow or whistle, one side of the mouth and cheeks acts properly, but the other side is motionless, or flaps loosely at the impulse of the expired air; so, in trying to suck, one side only of the mouth acts; in feeding, the lips and cheek are powerless, and, on account of paralysis of the buccinator muscle, food lodges between the cheek and the gums."—(Kirkes' *Physiology.*)

In *Cheyne-Stokes respiration* the respirations gradually increase in volume and rapidity until they reach a climax, when they gradually subside, and finally cease for from ten to forty seconds, when the same cycle begins again.

3. The early manifestations of pulmonary tuberculosis

are: (1) *Physical signs*: Deficient chest expansion, the phthisical chest, slight dullness or impaired resonance over one apex, fine moist râles at end of inspiration, expiration prolonged or high pitched, breathing interrupted. (2) *Symptoms*: General weakness, lassitude, dyspnea on exertion, pallor, anorexia, loss of weight, slight fever, and night sweats, hemoptysis.

OBSTETRICS AND GYNECOLOGY.

2. The pelvic diameters are easily remembered from the following table:

	Antero-posterior	Oblique	Transverse
Brim	4 inches.	4½ inches.	5 inches.
Mid-plane	4½ "	4½ "	4½ "
Outlet	5 "	4½ "	4 "

The fetal head has the following diameters: Occipito-frontal, occipito-mental, bitemporal, biparietal, suboccipito-bregmatic, trachelo-bregmatic, and mento-bregmatic. Of these the occipito-frontal is 4½ inches, the occipito-mental is 5½ inches, and all the others are approximately 3½ inches.

MEDICAL JURISPRUDENCE.

1. Any statement made by a dying person who believes that he cannot recover and that he is, at that very time, in actual danger of death. The statement need not be sworn to; it should be voluntary and sincere; and it is admissible as evidence in a court if the individual dies. An official or someone else should take down the deposition in the exact words of the patient, who should, if possible, sign the declaration.

3. *Symptoms* of poisoning by corrosive sublimate are: A burning pain in the mouth, pharynx, and stomach; the mouth and tongue are white; the vomitus is white, with shreds of mucous membrane, and tinged with blood; there may be bloody stools, also salivation.

Treatment: The antidote is white of egg, but too much must not be given at one time; this should be followed by an emetic.

4. "The time at which the bodies of the drowned will float varies with the temperature of the air, the water, the age, sex, and corpulence. As the human body is slightly heavier than water, it must remain submerged until it becomes lighter through the development of gases of putrefaction. Hence, in summer the body may rise within twenty-four hours. In salt water it will float sooner than in fresh; very fat bodies float sooner than lean ones; the bodies of women and those of young children sooner than those of men. Hence, in infanticide by drowning, the infant's body speedily rises to the surface."—(Reese's *Medical Jurisprudence.*)

5. "The postmortem appearances are neither certain nor characteristic. There is usually some fullness of the vessels of the brain; occasionally, extravasation of serum into the ventricles, very rarely of blood. Sometimes there is congestion of the lungs and other vascular organs. The blood is apt to be fluid. The stomach and bowels may be perfectly natural in appearance. The odor of opium may be observed in opening the body. It is hence impossible to diagnosticate a case of opium poisoning from the postmortem appearance exclusively."—(Reese's *Medical Jurisprudence.*)

6. Malpractice is a failure on the part of a medical practitioner to use such skill, care, and judgment in the treatment of a patient as the law requires; and thereby the patient suffers damage. If due to negligence only, it is *civil* malpractice. But if done deliberately, or wrongfully, or if gross carelessness or neglect have been shown, or if some illegal operation (such as criminal abortion) be performed, it is *criminal malpractice.*

7. The patient should be removed to pure air; inject normal saline solution; the patient should be bled; artificial respiration may be necessary; inhalations of oxygen under pressure have been recommended. The body temperature should be maintained by external heat

8. The *symptoms* are: Vomiting, purging, collapse; the secretions (including the urine) are suppressed, and the pupils may be dilated.

Treatment: Emetics, lavage, and mucilaginous drinks, with opium to relieve pain.

Lethal dose: Three beans have proved fatal.

9. *Symptoms*: Headache, vertigo, blindness, weakness, and neuritis.

Treatment: Lavage, and strychnine hypodermically

10. *Symptoms*: Contracted pupils, odor of turpentine on the breath, stertorous breathing, collapse, convulsions, odor of violets to the urine.

Treatment: Lavage, Epsom salts, and mucilaginous drinks, with opium.

BULLETIN OF APPROACHING EXAMINATIONS†

STATE.	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION		
Alabama*	W. H. Sanders, Montgomery	Montgomery	May	1-6
Arizona*	Ancil Martin, Phoenix	Phoenix	July	2
Arkansas*	F. T. Murphy, Brinkley	Little Rock	July	9
California	Chas. L. Tisdale, Alameda	San Francisco	Aug	2
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver	July	2
Connecticut*	Chas. A Tuttle, New Haven	New Haven	July	9
Delaware	I. H. Wilson, Dover	Dover	June	18
Dis. of Col'bia	W.C.Woodward, Washington	Washington	July	11
Florida*	J. D. Fernandez, Jacksonville	Jacksonville	May	15
Georgia	E R. Anthony, Griffin	Atlanta / Augusta	April / May	30 / 2
Idaho	J. L Conant, Jr., Genesee	Boise	October	1
Illinois	J. A. Egan, Springfield	E. St Louis	May	8
Indiana	W T. Gott, 120 State House, Indianapolis	Indianapolis	May	28
Iowa	Louis A. Thomas, Des Moines	Des Moines	June	—
Kansas	T. E Raines, Concordia	Topeka	June	11
Kentucky*	J. N. McCormack, Bowling Green	Louisville	October	22
Louisiana	F. A. La Rue, 211 Camp St., New Orleans	New Orleans	May	9
Maine	Wm. J. Maybury, Saco	Augusta	July	9
Maryland	J. McP. Scott, Hagerstown	Baltimore	June	—
Massachusetts*	E. B. Harvey, State House, Boston	Boston	May	14
Michigan	B. D. Harison, 205 Whitney Building, Detroit	Ann Arbor	June	11

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

West Virginia.—Under the new law which took effect on February 13, 1907, undergraduates are no longer permitted to take the State Board Examinations.

New York and Ohio.—Medical reciprocity no longer exists between these two States.

Fibromyomata in Uteri of Defective Conformation.—Andrea Boni describes an interesting case of fibromyomata in a uterus which had a single cervix with double vagina and fundus. The anomaly of the uterus was not diagnosticated until the examination previous to operation on the fibroids showed a double vagina, and the operation showed a double fundus. There were fibromata of both fundi, an ovarian cyst with a cystic tube on the right, and enlarged adnexa on the left. The cause of this anomaly is unknown, and we must be content to say that there is some force which prevents the union of the two ducts of Müller to form a single fundus at an early period of intrauterine life. The author has collected fifty-eight cases, to which he adds his own. He finds that fibroids occur in malformed uteri most frequently between the ages of thirty-five and forty-five, and they are rare after fifty. They are more frequent in nulipara and bear some relation to the presence of sterility. As uterus bicornis unicollis is the most frequent anomaly fibroids occur most frequently in that form. The symptoms do not differ from those of ordinary fibroids, and the diagnosis of the anomaly is first made at the operation for the removal of the tumor. (*Archivio Italiano di Ginecologia.*

Therapeutic Hints.

Angina Pectoris.—During the attack Barber recommends that amyl nitrite be inhaled at once; a capsule containing three or five minims should be broken in a handkerchief and the vapor inhaled; if this fails to relieve in a minute or two chloroform may be tried, which is best administered on a sponge in a smelling bottle by the patient himself; and for pain which is persistent, morphine, gr. 1-4 hypodermically, is required, which in a feeble patient may be counteracted by an injection of strychnine. At the same time, if at hand, the following stimulant should be taken:

℞ Spirit. ætheris.....mℳ xxx
Spirit. ammonii aromatici.....mℳ xxx
Aquæ camphoræ.....q. s. ad ʒj
Or failing that, fʒss of brandy.

Erysipelas.—The following local application is recommended by Meunier:

℞ Menthol.....gr. xl
Pulv. camphoræ.....gr. x
Olei betulæ.....ʒj
Guaiacol.....mℳ x
Petrolati liq.....ʒiij
Lanolini.....ʒiv
M. S.: Apply locally with slight friction.
—*International Journal of Therapy.*

Burns.—For burns of the third degree Prager uses the following dusting powder:

℞ Iodoform.....ʒi
Acidi borici.....ʒvii
M. S.: Apply locally over the area involved.

For extensive burns Leweson recommends the application of a 6 per cent. solution of aluminum acetate. After twenty-four hours' use of this a powder should replace it:

℞ Zinci oxidi.....ʒii
Bismuthi subnit.....ʒiv
Lycopodii.....ʒi
M. S.: To be applied locally, freely.

For the pain of severe burns Dale advises first a hypodermic injection of morphin and after the initial shock:

℞ Chloral. hydrat.....gr. x
Sodii bromid.....gr. xx-xxx
M. S.: Give in water at a dose, and every three hours until relief is obtained.
—*New York Medical Journal.*

Gonorrheal Rheumatism.

℞ Acidi salicylici.....ʒi
Mentholis.....gr. xv.
Guaiacolis.....ʒss.
Alcoholis.....fʒi
M. S.: To be painted over the affected areas, and the parts covered with cotton and oil silk.
—*Merck's Archives.*

Iron-Lemonade.

℞ Tinct. ferri chlor.....ʒiv
Acidi phosphoric. dil.....ʒvi
Spt. limonis.....ʒii
Syrupi.....ʒvi
M. S.: A dessertspoonful, in water, after meals.
—Goodell.

Dermatitis Venenata.—

℞ Sodii hyposulphit.....ʒi
Menthol.....gr. v
Spir. vini rect.....ʒi
Spir. æth. nit.....ʒi
Aquæ dis.....ad Oi
M. S.: Apply locally.
—*Medical Times and Hospital Gazette.*

Chamomile Enema.—For obstinate postoperative intestinal atony the following is often successful:

℞ Infus. chamomil.....ʒviii
Ol. terebinth rect.....ʒii
Carbo. lig.....ʒii
Aq. menth. pip.....ʒii
M. ft. Enema. S.: Inject warm.

Chapped Skin.—For chapped face or hands, or for sunburn, the following is highly recommended:

℞ Acid acet. dil.....
Glycerin.....āā. ʒi
Bismuth subnit.....q.s. ad. ft. massa.
S.: Apply locally.

Anorexia.—

℞ Tr. nucis vomic.....ʒiv
Ferri et. quin. citrat.....ʒiii
Tr. gent. comp.....ʒi
Vini xerici.....q.s. ad. ʒvi
M. S.: A teaspoonful in water before meals.

Medical Items.

Infantile Asthma and Its Treatment.—Méry, in his discussion of this subject, says that infantile asthma often exists in patients with adenoid vegetations or in those who have repeated colds. In certain cases the coexistence of other manifestations of arthritism have been noted. This affection must be differentiated from capillary bronchitis and from tracheobronchial adenopathy. Cardiac and renal affections must be looked for. The cause of this affection should be searched for and removed. Treatment of the attack consists in the application of moist dressings to the chest. In cases without fever warm applications are preferable.—*Journal de Médicine de Paris.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended April 19, 1907:

PULMONARY TUBERCULOSIS; SOME OF THE DETAILS OF ITS MODERN HYGIENIC TREATMENT WHICH CAN BE APPLIED IN TREATING THE PATIENT AT HIS OWN HOME.*

By HERBERT C. CLAPP, M.D.,

BOSTON.

VISITING PHYSICIAN TO THE MASSACHUSETTS STATE SANATORIUM FOR INCIPIENT CONSUMPTIVES AT RUTLAND; PROFESSOR OF DISEASES OF THE CHEST IN BOSTON UNIVERSITY.

In many walks of life a careful attention to details often explains the difference between success and failure. In none is this more true than in the treatment of tuberculosis. In my early professional days we sometimes advised consumptives to go logging in the Maine woods, to work on a ranch in Colorado, or to go lumbering in Minnesota. Very little more was said, and they were left in the main to regulate their own manner of living and to rely on their own devices. Occasionally one got well, but most of them died!

Now, if we know enough and are careful enough in our supervision, and if we have the cooperation of the patient, we can cure the great majority of incipient cases and some of those more advanced. The difference consists in attention to detail.

Since this subject has been brought so forcibly before the public within the past few years, many laymen and not a few physicians, with a big swing of the pendulum from their former pessimism, have come to think that the cure of consumption is now a very easy matter; that there is no need of drugs, nor even of physicians, but that all that is really necessary is to live in the open air and to eat plenty of good food. Would that it were so! We may be sure that shipwreck would inevitably be the lot of large numbers of those who followed this partially good advice if they did nothing more. A greenhorn may sail a boat when everything is propitious, but wait until the storm comes! A novice, after a few lessons, may seem to run an automobile well, but surely pride goeth before a fall, and trouble on trouble is his before the season is over. What does he then think of detail?

Nobody now considers climate so important a factor in the cure of tuberculosis as formerly. We now know that the disease can be cured in almost any climate. It does not make so much difference where one lives as how one lives. Although there are sometimes advantages in seeking another climate, yet many people for one reason or another, even if they have money, will prefer to stay at home. Good care at home is far better than the best climate anywhere with less care.

In sanatoria supervision by the physician and nurses can be more perfect, and more careful attention can be given to detail than in a private house. It is easier for a victim of tuberculosis to be good where everybody else is good, and the force of example is strong. The new patients are greatly encouraged and helped by the evident improvement of those who have entered a few weeks ahead of them; and this encouragement from their fellows ensures more willing obedience to possibly irksome rules. A new patient, entering among older ones who have learned some lessons, does not dare to object to this rule or that or to growl too much, for fear of the ridicule of his comrades who have by pleasant experience proved the value of the rule. Thus much time and effort are saved to the physician and nurse in the supervision which in some form or other is absolutely necessary.

But there is not now nor will there ever be sufficient sanatorium accommodation for all, and even if there were, many people cannot or will not go to a sanatorium.

Although it is not so easily done, yet patients can be cured in private practice if, on the one hand, the physician is sufficiently posted and will take time enough to give definite directions and to see that they are carried out; and if, on the other hand, the patients have will power, character, and intelligence enough to obey the rules understandingly and faithfully. It may be necessary to write out for these patients the directions very carefully, giving them the more general ones in print, and to impress on them as forcibly as possible the importance of carrying them out conscientiously. If they become careless in little things, their carelessness may put them back a long time or even cause their death, as has frequently been demonstrated.

To get well is a constant fight, but it is worth the while. It requires much patience, perseverance, and great self-denial, sometimes even heroism, on the part of the patient to submit himself to the necessarily rigid restrictions.

If a physician has several patients to treat in the same locality, it will be a great saving of time to him, and may be of some advantage to his patients likewise, for him to form a tuberculosis class, according to the system originated by Dr. Charles S. Miner of Asheville, S. C., and practised by him for several years among his well-to-do patients. Practically the same system has been carried out for over a year by Drs. Pratt, Hawes, and others in Boston, among the very poor, where it has been successful beyond reasonable expectation. Of course, in the latter cases financial aid in the way of food, tents, blankets, etc., has often been necessary and has been furnished by Emanuel Church and other charitable agencies. But the success of this latter work shows that even in the slums of a great city on the seacoast much can be done by inducing poor people to live properly by day and by night and to breathe the fresh air in tents on housetops high above the street dust, or in less crowded districts in tents or shacks in the

*Read before the Hughes Medical Club.

backyard, or on a piazza or fire-escape, or balcony. Of course, it is better still out in the suburbs; but careful medical supervision in a bad locality brings better results than a free and easy life in the best regions obtainable. The members of these classes bring to each meeting, once a week or oftener, their record books containing reports of the morning and afternoon temperature and pulse, taken by themselves, the amount of exercise and rest, number of hours in the twenty-four spent out of doors (often over twenty), cough, sputum, amount and kind of nourishment and hour at which it is taken, etc., etc. They are weighed once a week, the gain in weight is announced, and they are given a plain talk containing encouragement and directions for proper living. They are also regularly visited by a nurse, to see that they are carrying out these directions. Their lungs are examined once a month. This combination method is surely very helpful with poor people, and certain modifications of it may sometimes be found useful with people in better circumstances.

Fig. 1.

It is manifestly impossible in the limits of a short paper to present all the necessary details. It it also impossible, no matter how much space or time is at hand, to give directions so explicit as to cover all exigencies or emergencies in individual cases. In this, as in many other diseases, very much must be left to the judgment of the experienced and resourceful physician. Patients who have any regard for their own welfare and who do not care to take too many chances should put themselves under the supervision of a competent physician and be guided by him rather than try to manage their own cases alone. A few of the most important points are here given.

Out-of-Door Life in Warm Weather.—In the summer in New England, except in the crowded parts of cities and large towns, it is easy enough to live out of doors all of the time without much urging; and when indoors all of the windows can be kept open with very little inconvenience. Owing to the fact that the circulation of the air is less active in the summer, it is very advantageous to the patient to *sleep* also out of doors in this season; whereas in midwinter in New England a fair sized bedroom with two or more open windows is by far more convenient, and is practically good enough in most cases, superseding the necessity for anything more strenuous.

In summer a patient can sleep on a piazza or porch, preferably on the second floor. If it can be so planned, it is better not to have the porch face the east, for the rising sun wakes one too early. Nor should it face the direction of the most frequently prevailing storms. If the sides of the house do not at all times intercept violent winds, a canvas curtain can be arranged so as to be put up at short notice, or a screen of glass or boards. Gentle zephyrs or moderate breezes should always be welcomed, whether out of doors or in a room. To this extent drafts are beneficial, when the air is all around one, but not in narrow shafts or pencils from a slightly open window striking on the body, especially when the body is covered with perspiration. A consumptive after a little while delights to feel the play of breezes about his face, and he must have at all costs air which is not stagnant. A very powerful wind (especially if it is cold) is, however, unfavorable and needs to be guarded against. If one sleeps on a piazza in summer he needs to have a mosquito netting of cloth or wire tacked up to exclude insects, and if the piazza is on the ground floor, the netting should be strong enough to keep out cats and dogs likewise. A common tent can be utilized for sleeping out, but it should have a board floor raised from the ground, and at least two of its sides, if not all four, should be more or less open. An occupied common tent with its canvas spiked to the ground all around, as some use it, in the morning contains air which is perfectly horrible. If canvas were as pervious to air as some people think, it would be useless for sails of ships. Army tents are apt to be stuffy.

A tent with a conical shape like the Indian "tepee" and open at the top affords fair ventilation if a space is left between the walls and the floor (which is raised from the ground) through which the air enters and rises, going out at the top. The Gardiner tent is built on this principle and costs about $100. Prof. Fisher of New Haven a few years ago invented a remarkably ingenious "up draught louvre tent," and lately a sensible square tent-shack, which also combines the advantages of the rotating kiosk. Neither is patented.

Fig. 2.

Still better than a tent is a shack made cheaply of boards, with overhanging eaves, with windows, and with one side entirely open and furnished with

curtains to be lowered in case of a driving storm on that side. Some like a hammock swung between two trees, with a canvas cover for a watershed; but most hammocks become very uncomfortable after one or two hours.

In cities the flat roofs and fire-escapes, and sometimes the back yards have been utilized for sleeping as well as for sitting out daytimes.

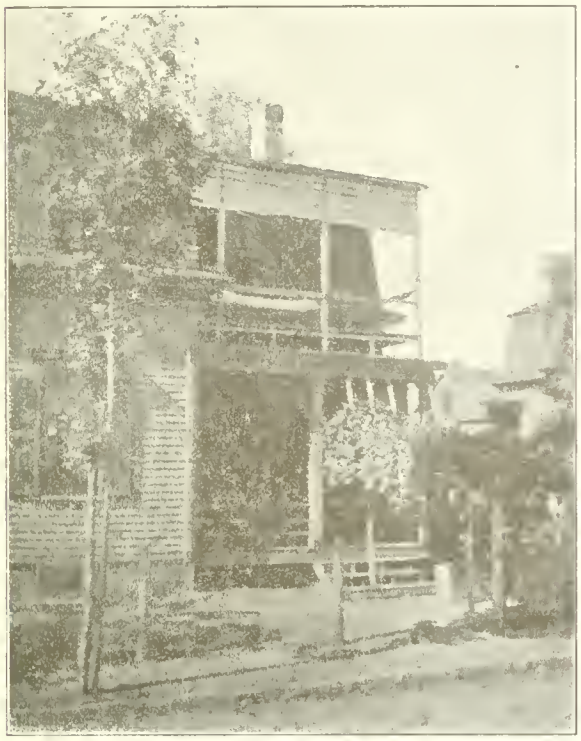

Fig. 3

In hot weather a patient should not have his head exposed for too long a time to the direct rays of the sun, and in great heat he should seek the shade for his whole body.

The house of the patient must have an abundance of sunlight and good ventilation, and therefore must not be too closely surrounded by trees, must stand on ground well drained to avoid dampness, must be kept clean by means of dampened cloths or mops, and must not have the dust moved from one place to another by dry sweeping, must have rugs instead of carpets, and no heavy draperies.

Night Air; Rain and Snow.—A great many people, even after having been convinced of the wisdom of exposure to fresh air in pleasant weather, are even now horrified at the idea of a "consumptive" being out in the damp, raw, or foggy weather or in rain or snow storms, or in having the windows open nights in such weather. First, as to the latter, some still imagine that night air is bad air, even if the sky is clear. After persuading them that the opposite is true, we should address ourselves to the harder task of inducing them to let the night air in, even in stormy weather, provided that the rain does not actually wet the bedclothes or soak through the floor and loosen the plaster ceilings of the room below. A few flakes of snow in the room will do no harm, unless the bed is wet by its melting. Most of a beating rain can be kept out without excluding the air, if the outside blinds are closed, the windows remaining open. If there are no blinds, and if there are enough windows in the room (four or more) and on different sides of it, during the actual downpour the windows on the windward side can be closed more or less and on the other side left open. If the room has not enough windows, additional air can be obtained right along by taking out all the sashes. This I have often done with advantage, especially in the warmer parts of the year.

A consumptive if well protected should not hesitate to go out because it rains. He should continue to sit on his piazza, if the overhang of the roof is sufficient to prevent the rain from actually falling on him. He should not abandon his walk, but put on his waterproof and rubbers or heavy boots and carry an umbrella. If when already out he gets caught in the rain without these safeguards, it will not hurt him to get wet, if he continues to walk and thus keeps warm. The same principle applies with rowing, riding horseback, or any other exercise. If he is tired and feels obliged to sit down in his wet clothes, if covered up well with a blanket or extra clothing, he may rest for quite a while without injury. But, on the other hand, if he has no extra covering, and sits or drives until he is thoroughly chilled, aggravations or complications are very apt to follow. In either case he should on reaching home take a dry rub or a bath and put on dry clothing and drink something hot.

Out-of-Door Life in Cold Weather.—The real task in making people take the fresh air is appreciated when cold weather comes. Then comes the tug of war. At least, this is so to begin with. After a patient has gotten used to it and has become convinced by actual experiment that he is not going to freeze, and is conscious of great improvement in his symptoms, he generally delights in it, and often rebels if asked to go back to his old ways; becoming,

Fig. 4

in fact, a so-called fresh-air fiend. But in the breaking-in process perhaps all our persuasive powers may be necessary, and even a little bulldozing. Here much of our success depends on how we carry out details. Some take to this life naturally, but most people need a good deal of instruction and encouragement. Our strongest argument with them is the fact that practically everywhere consumptives

make better and more satisfactory progress in winter than in summer. All sanatorium physicians in this country and abroad will testify to this fact.

All patients have to sit out much of the time; some have to sit out all of the time, not being allowed any exercise at all. The location for this sitting out is important. Sanatoria are generally built, if possible, on a hillside, with a hilltop to keep

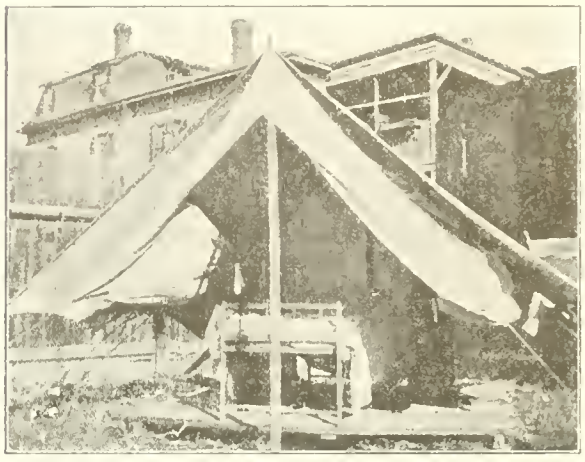

Fig. 5.

off the worst winds, which generally come from the north and west. The exposure should be mostly to the south, with the additional purpose of getting the sun all day. In a private house it is nice to have the piazza or balcony on the south side, in a jog or angle of the house for protection against the wind. If not, this should be obtained by means of some kind of a wind-shield. Glass is nice because it admits the light, but other material will do. This does not mean a glass-enclosed piazza or what is sometimes called a sun-room. In winter the strong winds (generally from the northwest) must be kept off, as they have a more cooling effect on the body than a still atmosphere many degrees lower. Trees often make a good windbreak. If the patient can afford it, a fine protection is secured by a revolving shed (a kiosk) enclosed on three sides, so as to meet and oppose the changing winds. A movable canvas curtain on a piazza, however, does very well. The best kind of a chair to sit out in is a steamer chair, of which there are several modifications and various prices, from $2 to $20. The more expensive have comfortable adjustable backs and cushions or mattresses. The steamer chair position is easiest to maintain for long stretches of time. Even more important is the fact that when the legs are mainly horizontal, they can be kept warm by wraps, which is almost impossible in cold weather if the feet touch the floor or ground.

During all seasons the patient should aim to be out of doors at least eight of the day hours, and more if he can. This may be reduced a little if the patient lies on his bed with open windows for an hour after the noonday meal, and if he goes to bed early, to have a long night in the fresh air. Counting these times, he should if possible be in the fresh air twenty out of twenty-four hours. He should have a warm room in which to dress, undress, and take his morning cold bath, as well as for his meals; and occasionally he may be allowed a little more liberty, but not much. If he is strong enough to see friends, he can entertain them on the piazza or other place where he is sitting out. He surely should not go to places of amusement or religious meetings, where the air is bad on account of crowds of people or of burning lamps or gas.

Occasionally, but not often, it happens that a patient, after experiencing benefit from the fresh air treatment, becomes *over*-enthusiastic in exposing himself to very cold and boisterous weather and needs to be restrained, but the opposite is far more common.

In very cold weather it is sometimes wise to introduce a certain amount of artificial heat into the room, the windows still being open. Many people confuse cold with fresh air, and heat with foul air. Even they on reflection will recognize the falsity of this and the fact that the air in a room may be very foul and unbearable with a temperature near zero, and pure at 90°. Here again we have to emphasize anew the statement that fresh air is what we should cry for and not necessarily cold air. The patient must have fresh air all the time; and yet he does best if the air is as cold as he can stand, while he is exposed to it constantly.

Clothing.—I often say to patients, "I do not care how you dress, provided you are fairly comfortable." Whether it is wool or cotton or mixed, linen mesh, silk, fur, leather, or paper, it makes little difference. Some need more and some less. Some lean towards too much clothing on the ground that they are delicate. The effort should be to wear the lightest weight and the least amount of clothing that will keep one fairly comfortable.

According to an old custom, a man having once put on his winter clothing in the fall, or a woman her furs, should never leave them off until the calendar says a certain spring month has arrived. How ridiculous! Instead they should change back and forth as the weather changes each day. They should suffer neither from the heat nor from the cold.

Cotton and wool mixture for underclothing is the best for most people and is not costly. Sweaters, cardigan jackets, chamois vests are all right. For walking, a short leather jacket, such as hunters wear, and lined with lamb's wool, is better than a heavy and clumsy fur coat, which, however, in its turn is far preferable for sitting out. Nowadays,

Fig. 6.

good warm fur coats can be bought for $15 or more. I have seen great satisfaction experienced by sitters out (not so much by walkers) from a long, heavy, shaggy, woolly waterproof coat made in Buffalo, called the Saskatchewan, which seems to defy the attacks of the coldest weather. I have kept perfectly warm in one in long sleigh rides with the thermometer below zero, when I should have suf-

fered in my fur-lined overcoat which cost seven times as much. Their price is only $18 for men and $20 for women. Now quite a number of our country doctors are using them in their long daily rides. If a patient can afford only one coat, however, they will not do, because they are too warm for most days. A coat of any kind should have a high collar, and there should be elastics in the sleeves at the wrists, or something else to prevent the wind going up the arms. A Canadian sash about the waist adds to its warmth.

For the hands common mittens of wool or of fur-lined leather are far more effective than gloves in zero weather, and they should be large and loose. If it is not quite so cold, and the patient is anxious to use his hands, he can put on thin cotton summer gloves, and over them warm mitts without fingers and made of worsted, or long worsted wristlets coming well down over the hands.

The protection of the feet is very important, and if they are not properly clothed much suffering follows. The shoes should not be tight. Rubber soles and heels are splendid when the ground is wet or cold. If they are not available, common rubbers should always be worn in rainy and especially in slushy weather. Arctics over the shoes for walking in the snow or for sitting out are much worn; less often felt shoes or soft moccasins. For sitting out or for riding foot-muffs made of quilted material stuffed with cotton and with layers of newspaper are good. If money is plenty, the automobile foot-muffs made of fur are satisfactory, and hot bricks or soapstones are often a necessity.

For the head a cap of cloth or fur or a tam-o'-shanter is most used. It should pull down over the ears or else have ear-tabs. A Derby hat or a woman's stiff hat will not allow the head to rest against the high back of the chair.

Before sitting out, the patient should be well wrapped up below the waist with steamer rugs or a fur robe, or common blankets or horse blankets, the blankets being perhaps five or six feet square. There is something of a knack in putting them around one to the best advantage. Some kind of a rug or blanket over the chair or hammock before getting in is a necessity, just as an extra mattress or a blanket over the mattress will add greatly to comfort when sleeping on a bed with windows open.

Sleeping Out in Cold Weather.—In our rigorous New England winters it is not very often really necessary to sleep out of doors. If the bedroom has two or more windows, generally enough air will circulate. But if the patient is anxious to sleep out it can be done, and no doubt it is more thorough in critical cases. A tent in winter is not so desirable as a rough shack containing a stove and open on one side, the open side to be closed with a curtain when dressing. Or without the stove and curtain the patient, to wash and dress, may slip into the warm house if it is near. Better still is a second floor piazza, properly protected.

Best of all, if the patient can afford it, is a sleeping porch specially built onto the house. Fig. 1 shows a remarkably nice one which an intelligent and educated gentleman had attached to a jog in his house last fall in the suburbs of Boston, and which he has slept in every night during this intensely cold winter, with great comfort and advantage. I have seen him several times in consultation with his physician, and he is very enthusiastic and loud in his praises of its merits. It is on the southeast side of the house and thus protected from the most common winds. For access from the house a window was cut down to the floor, making a door. The canvas curtains can be easily raised and lowered at will, and he can dress and undress and bathe in a warm room in the house. The whole structure cost about $100. It would be better still if the eaves projected more.

Fig. 2 shows an ingenious sleeping porch, large enough for two beds, built by another patient of mine in the Berkshires at a cost of $45, which has proved very successful. There being no piazza nor angle to the house, this was built against its flat side. As this was a hired house, it was put up with an eye to its easy removal without defacement to the walls, and the window was not cut down, boxes inside and out serving as steps. I have several times recommended others of similar pattern. Cheaper porches and also tents in actual use are shown in Figs. 3, 4, 5, and 6, from the third report of the Cambridge Anti-Tuberculosis Association.

To sleep out of doors in one of these porches a patient must dress especially for it. Some need more clothing than others. Dommet or outing flannel makes a fine, warm and inexpensive nightshirt, which should be made large and come to the floor when the patient is standing. Under this can be put on a woolen shirt and outside of it a sweater. A worsted skull cap, coming down over the ears and nose, is desirable on cold nights. Over this some wear a knitted helmet, covering the head, neck, and shoulders. Bed socks of wool or worsted are desirable, and if these do not keep the feet warm a hot water bottle or hot soapstone should be used. Kenwood sleeping bags, warm and well padded, closed in at the feet and coming well up around the body, are very comfortable for camping out.

The bed should either have two mattresses for warmth, or newspapers under one, or a blanket over one. A common amount of bed clothing in zero weather is eight thicknesses of woolen blankets, besides a quilt and either a down puff or an overcoat thrown on top. Old-fashioned comforters are too heavy. Down puffs, on the contrary, are very light and warm, and as commonly found in the stores cost about five or six dollars, with sateen covering. If made larger and thicker and of a higher grade of down and covered with silk, the price may be from $20 to $25.

If it rains and there is danger of the bed getting wet, some kind of waterproof cloth or a horse blanket can be thrown over all. Some like woolen sheets, but with all the bed covering mentioned above most prefer cotton. Two pillows may be used, one being tucked in around the shoulders and the other in front, to keep the cold air out, the head resting where they overlap. Of course, as the weather moderates the amount of bed clothing must be reduced so as not to make the patient too warm.

Exercise and Rest.—The careful regulation of the exercise is one of the most important features of the treatment. Very often it has happened that one act of indiscretion in this direction has entirely spoiled the patient's chances for recovery, and still oftener it has put him back for weeks or months, when he was previously progressing finely. More consumptives have been killed by overexertion than by anything else. In no particular is there more call for judgment and experience on the part of the physician and nurse. No absolute rules can be laid down. The physician must individualize his patient. The stage and activity of the disease and the special symptoms are largely the determining factors.

Exercise should never be pushed to the extent of

inducing exhaustion or fatigue which cannot be recovered from by a little rest; nor should it be carried to the extent of inducing increase of temperature, shortness of breath, or marked acceleration of the pulse, or cough, nor should it be taken too soon after a hemorrhage. A good rule to determine whether or not exercise really increases the temperature is to have the patient rest for twenty minutes or more after exercising and to take the temperature after this rest. If it is not elevated then, no harm has been done.

When the patient first comes under observation he should generally be kept still for from one to three or four weeks, even if his pulse and temperature would otherwise allow action. Then he can take a fresh start, after his rest has given him a surplus of energy to draw from.

If a patient's afternoon temperature is over 101.5° he should be kept in bed for awhile, as a rule. If over 100.5° he should be recumbent most of the time; if over 99.5° he should sit out without exercise on that day and on the day following. All should observe the quiet hour after the noon meal by lying down. In many cases it pays to keep the patient quiet after each meal; and in some, rest should be enjoined for half an hour before each meal, so that the stomach should not undertake its work in too tired a condition. If the morning temperature is 99° the rule is to take no exercise on that day. When a patient begins to sit up after being abed, he should not be up for long at a time. When he begins to walk about he should increase his amount very gradually. Worry and mental excitement or any decided mental exertion must be guarded against as well as physical efforts. A game of cards will sometimes raise the temperature decidedly. When his condition allows and he increases his exercise more and more, he should still be watched carefully to see that he does not overdo. Walking is the first thing, at the outset very slow, then faster on a level, and then gentle hill-climbing at a slow pace. As he progresses, horseback riding, if the horse is easy, and carriage or sleigh, or slow auto-driving are allowable, and a little later croquet or golf, or mild rowing, or skating, or garden work. Tennis and baseball are more violent and are only to be undertaken by those whose disease is practically arrested, and then only with care. Football is out of the question. In all games the influence of the competitive element should be reduced as much as possible. The consumptive should never exercise for the purpose of developing muscle and of becoming an athlete.

When the call for rest is a loud one and the rest needs to be mental as well as physical, complete seclusion is often advisable; or if this tends to depression, the patient can be rolled from his single room to the veranda, when for a short time each day he can see a few of his fellows.

During the active progress of the disease there are so many indications either for limiting exercise more or less or for entirely forbidding it, that some patients almost get the idea that they are never again to resume it. Often a patient, when teasing to be allowed to go home from the sanatorium a little before the proper time, has told me that he would promise not to do a bit of work or take a bit of exercise all winter if he could go. Of course, more or less exercise is necessary for all of us. It promotes nutrition, assists the aeration of the blood, strengthens the nervous system, and helps the elimination of various substances through the lungs, kidneys, bowels, and skin. Just as soon as the contra-indications are done away with, exercise both of the body and mind must be resumed. If prolonged rest really has made the patient lazy, as sometimes happens, he should be encouraged to exercise to an extent proportionate to his condition.

SURGERY IN DIABETES.*

By JOSEPH WIENER, M.D.,

NEW YORK.

ADJUNCT ATTENDING SURGEON, MT. SINAI HOSPITAL.

THE subject of surgery in diabetes is of such vast importance, our textbooks say so little on the subject, and there is such a diversity of opinion among medical men, that a careful study of the entire subject has seemed both profitable and desirable.

Some authors would prefer to see only absolutely necessary operations done. Others warn of the dangers of coma and gangrene. Still others, and this growing class includes one who is peculiarly fitted to decide the question, namely Naunyn, hold that the old rule of not operating in the presence of diabetes can no longer be maintained. Israel, writing in 1882, advises that only imperative operations should be done on diabetics. No plastic operations should be undertaken; no benign tumors removed. He advised postponing operation if posible until the sugar had disappeared from the urine. Tuffier, in 1888, advised against operation unless the sugar in the urine could be reduced by diet. Among the more modern writers Kümmell is one of the most enthusiastic. In his experience diabetic patients stand major operations very well. According to Baldy the belief that diabetes contraindicates operation is a superstition.

At the very outset we must divide the entire subject into two parts: 1. Lesions or diseases which have developed independently of the diabetes. 2. Lesions or diseases which have developed as the result, or as a complication, of diabetes. With the first class of cases this paper will have but little to do. A diabetic patient who requires an amputation of the breast, or the removal of a kidney, or even a plastic operation, should have that operation done. And the wounds will heal, and the mortality will be but little different from the non-diabetic cases. The writer would refer here in passing to his three cases of prostatectomy in diabetics reported elsewhere, which made as good recoveries as the ordinary cases.

When the disease for which we are called upon to operate is the result or a complication of the change in the tissue metamorphosis, we are confronted by a much more serious problem. And it is with this problem that this paper will chiefly deal.

1. Changes in Metabolism.—As is well known, we find in diabetes an increase in certain normal excretions, together with the presence of certain abnormal excretions. So we find in the urine of diabetics glucose, acetone, diacetic acid, oxybutyric acid, and an increased excretion of ammonia. The exact rôle which these different ingredients play is not yet definitely settled. We know by experiment that the virulence of pyogenic bacteria is increased by the presence of sugar in the tisues. The sugar in the blood and in the tissues makes a favorable culture medium for the growth of bacteria, provided the percentage of sugar is not too great. If the medium contains much sugar the growth of bacteria is hindered. The blood of diabetics contains 0.2 to 0.8 per cent. of sugar, rarely more than 0.5 per cent. And it is just this percentage of sugar

*Read before the Eastern Medical Society.

that is most favorable for bacterial growth. There is a common but erroneous belief that the greater the amount of sugar excreted the worse the prognosis. The worst feature is the acidity of the blood. The presence of these abnormal acids in the blood injures the tissues and makes them more prone to infection. These acids are furthermore in all probability causative factors in producing premature arteriosclerotic changes. The increased excretion of ammonia, the presence of acetone, diacetic acid, or β-oxybutyric acid, if it cannot be reduced by diet, certainly makes the prognosis worse. Phillips holds that no operation save of the extremest urgency should be done if more than one gram of ammonia is excreted in twenty-four hours, until this has been reduced to normal. He further advises that an operation should be postponed if diacetic acid is present, even though there is no marked increase in ammonia.

2. Arteriosclerosis plays a very important rôle in diabetic gangrene. The first systematic examination of the vessels in this disease was undertaken by Fr. Koenig in 1887. He found marked arteriosclerosis and calcareous deposits in the walls of the vessels. In from 65 to 100 per cent. of the cases various authors have found these changes in the vessels. Some patients who do not know they have diabetes complain for a long time before the development of the gangrene of symptoms due to faulty circulation. These symptoms are coldness, anesthesia, paresthesia, or severe pain in the limb. Sooner or later the black spot that is the precursor of the gangrene appears on one toe, or on the sole of the foot. The arteriosclerosis causes either a marked narrowing of the lumen or even a complete obliteration. This applies to veins as well as to arteries. As the process is progressive, less and less blood is carried to the furthermost part of the extremity. Finally there is almost complete stasis. Then thrombi form in the capillaries and terminal vessels, and the gangrene begins. Or, there may be a thrombosis of one of the larger vessels which is quickly followed by gangrene. Or again, the gangrene may result from an embolus lodging in one of the larger vessels; this is rare.

The rare occurrence of diabetic gangrene in women is another proof of the importance of the arterial changes. Out of 118 cases only thirteen were in women. The upper extremity is very rarely affected, because the arterial changes are found in the lower and not the upper extremity. It is now generally held that the gangrene is largely dependent on arterial changes, and that in the absence of arterial changes gangrene will not develop in diabetes.

3. Coma.—We all know that in a certain number of cases, even following minor operations, diabetic patients go into coma and die. Even a prolonged anesthesia, not accompanied by any operation, may bring about a fatal coma. Conversely, coma may follow an operation for which no anesthetic had been given. At times the most trivial incident or accident will bring about coma, while in other cases a severe injury, or an extensive operation will cause no ill effects. The fear of an operation, loss of blood, starving and purging before operation, all have an influence in causing coma. Hirschfeld emphasizes the fact that diminished nutrition is a marked predisposing cause of coma. Psychic influences, worry, and overfatigue, likewise predispose to coma. In diabetic coma the urine contains one or more of the following products: acetone, diacetic acid, β-oxybutyric acid. According to Naunyn, if more than three grams of ammonia per diem are excreted, there is great danger of coma; if the amount exceeds four grams, coma is inevitable. We often, in non-diabetic cases, find acetone or diacetic acid in the urine after a prolonged anesthesia. Kast and Master found after prolonged chloroform anesthesia increased proteid destruction, with an increase in the amount of acids excreted. We thus see the danger to a diabetic of general anesthesia. If we accept the coma as the result of an acid intoxication, it is not wise to reduce the percentage of sugar by a strict meat diet, because an exclusive meat diet will increase the acidity of the urine.

4. Diet and Medication.—Here again we must differentiate as to whether the disease for which we are operating is the result or a complication of diabetes, or whether it has developed independently of the diabetes. If the disease is merely an intercurrent one, the indication for dieting is not very urgent. Indeed, if we are dealing with patients of advanced years, whose general condition is none too good, we would probably do more harm than good by a strict diet. Their nutrition would suffer, and though we might be able to reduce the amount of sugar in the urine, we would be dealing with a two-edged sword. In cases of diabetic gangrene, if there is time, a moderate antidiabetic diet before operation will often be of benefit. If the excretion of ammonia is in excess, sodium bicarbonate should be given daily in large doses until it becomes normal. If the stomach will not tolerate the large amounts of soda, it can be given by rectum. The dangers of coma and of sepsis are lessened by the alkaline treatment, which should be kept up for some time after operation. Rumpf suggests sodium citrate in place of the bicarbonate. Salol or sodium salicylate are also useful. Noble made it a rule to employ a moderate preliminary diet and to give codeine and strychnine. After operation he advises a strict diet, codeine, morphine, and salt solutions by rectum and subcutaneously. He stated, however, that the dieting and medication before operation had not, in his experience, reduced the number of cases of coma. The giving of large amounts of water before and after operation is of great importance, just as refraining from removing too much fluid from the body by starving and purging is important. It may be safer to operate in the absence of sugar, but, as was pointed out above, the sugar should not be made to disappear by increasing the acidity of the urine (by an exclusive meat diet), because the greater the acidity the more likely is coma. With a good general condition and a large percentage of sugar, the prognosis is better than with a poor condition and a small percentage of sugar. Rudisch has recently pointed out that the administration of atropine in doses of gr. 1-150 to gr. 1-100 three times a day, together with codeine, will very rapidly and very markedly diminish the amount of glucose in the urine. If this method proves satisfactory it may take the place of dieting before operation. It certainly is not open to the objection of increasing acidity.

Phillips collected thirty-four cases that were given preliminary treatment with six deaths, four from sepsis and two from coma. In eleven other cases no preliminary treatment was given and four died, two from sepsis and two from coma. The number of cases, however, is too small to draw conclusions from, although a larger proportion of the dieted cases in this series recovered. Most authorities agree that a moderately strict diet is desirable after operation.

5. Technique of Operation.—The principal dangers of operations on diabetics are: 1. The anes-

thetic. 2. Infection. 3. Hemorrhage. Ether and chloroform should be avoided as much as possible. From all reports ether is a little less dangerous than chloroform in these cases. Nitrous oxide, spinal anesthesia, and local anesthesia should be the methods of choice. If local anesthesia is used, only small quantities of fluid should be injected into one locality to prevent too much stretching of the tissues. Many major operations can be done under laughing gas if given by a skilled anesthetist. The writer was able in one non-diabetic case to do a nephrectomy lasting a half hour, and only gas was given.

The field of spinal anesthesia is also a broad one. The writer recently performed an amputation of the thigh in an old lady under spinal anesthesia. A hypodermic injection of ¼ gr. of morphine was given, and the patient not only suffered no pain, but was actually asleep during the operation. Gersuny collected eighty-six narcoses from various sources without a single case of coma. Ether and the A. C. E. mixture were the anesthetics used. Witzel has reported in a similar vein. But, as was pointed out above, it is not only the anesthetic that brings on coma. The dread of operation, the loss of fluid by preliminary purging and fasting, are also contributing factors. All these elements should be reduced to a minimum. It is well to operate in the morning, after the physiological fasting of the night. If neither ether nor chloroform is used, the patient can have his ordinary food up to the time of operation. There will then be no vomiting after operation, and the patient can take nourishment very soon. We have seen why diabetics are peculiarly prone to infections. Everything possible should be done in preparing the field of operation, and, during the operation itself, to prevent infection. Asepsis should be most rigid. Antiseptics, inasmuch as they lower the vitality of the already compromised tissues, should not be allowed to come in contact with the wound. Rubber gloves should be worn, and the tissues handled as gently as possible. The operative technique as well as the dressings should be as simple as possible. The loss of blood should be reduced to a minimum. Reynier lays great stress on the absence of the knee jerks as giving a bad prognosis. He claims that no major operation will be successful if the knee jerks are absent. Honzak advises against operation in the presence of chronic interstitial nephritis. On the other hand, as Grossman after an exhaustive study of the subject points out, the results of operation under strictest asepsis are improving from year to year. And, in view of the sad results of non-operative treatment, an operation should often be done even where the outlook is bad. In doubtful cases the urine should be examined for the percentage of sugar, acetone, diacetic acid, and -oxybutyric acid. The total amount of ammonia excreted should be determined. If there is serious disease of liver, heart, or lungs, the prognosis of operation is bad. If there has been much loss of flesh not depending on the surgical lesion, it will be well to improve the general condition before proceeding to operation.

6. Fractures.—Fractures in diabetics heal well, though often more slowly than in healthy subjects. Phillips reported three cases from St. Bartholomew's Hospital which united promptly and well. He reports, however, an empyema following a fracture of a rib which ended fatally. Naunyn, in his monograph on diabetes, stated that he had never seen an empyema in a diabetic. He further states that suppurative inflammation of serous membranes is very rare in diabetics. Legendre reports a perfect result in four weeks in a fracture of the humerus; the woman was sixty years old. Phillips reported an excellent result in a subtrochanteric fracture of the femur in a man of fifty-eight. He also reported a good result in a man of fifty-five, with a Pott's fracture. Spitzer reported a case of fracture of the clavicle in a man of forty-six. There was 4 per cent. sugar and 1-20 per cent. ammonia. Sodium bicarbonate was given freely. There was improvement for four days, then the man became worse and died of coma, evidently due to shock, on the seventh day. Smith and Durham quote three cases in which fractures took four to five months to consolidate, and two in which non-union occurred. Naunyn states that imperfect union may occur even though at the time no sugar is excreted. He also refers to the frequent absence of pain in fractures in diabetics. He reports twelve cases of fracture. Three died; one after a primary amputation, one from coma induced by the shock of the accident, and one from pyopneumothorax caused by fractured ribs. In five cases there was delayed union or non-union; in four cases the union was normal. According to the researches of Toralbo, Van Ackeren, and Gerhardt, diabetics often excrete such an excess of phosphoric acid and lime salts over the quantity in the food ingested, that these ingredients must come from one of the tissues of the body. This can only be from the bones. Gerhardt attributes this to the increased acidity, and states that the administration of alkalies diminishes the excretion of lime. It would therefore seem rational in these cases to administer alkalies in order to lessen the excretion of lime, and perhaps to administer lime salts in order to make up for the increased excretion.

7. Operations for Diseases Not Due to Diabetes.—Noble of Philadelphia, in a paper on this subject, called attention to the widely spread belief that the healing process in wounds in diabetics is markedly interfered with, and that the sloughing rather than the healing of wounds is to be expected. Frequently have we heard doctors say that they would like to have a certain patient operated on, but that the patient had diabetes, and they had therefore advised against operation. Noble reported seven cases, one amputation of the breast, a ventral hernia, a vaginal hysterectomy for prolapse, a colpoperineorrhaphy, a post-operative hernia, a case of appendicitis, and a rectovaginal fistula. Of these seven cases one patient died in coma on the sixth day. This woman of fifty had had diabetes for many years, with a large excretion of glucose. In the other six cases the healing of the wounds was not different from that in patients without diabetes. The writer has elsewhere reported three cases of prostatectomy in which the wound healing was satisfactory. Sternberg reported sixteen major operations from Gersuny's clinic. He concludes that any necessary operation should be done, that a preparatory diet is desirable but not absolutely necessary. The operations included two cases of amputation of the breast, one case of cancer of the rectum that survived operation two years, one case of cancer of the jaw that survived two extensive operations, one case of myoma of the uterus removed by morcellement, one case of cholecystitis, and one case of prolapse of the vagina with rupture of the perineum, necessitating two extensive plastic operations within three months. Four of these cases had severe diabetes, one case had 7 per cent. of sugar. Noble collected sixty-nine cases involving the breast, the female genitals, and the abdomen; fifty-two cases recovered and seventeen died. From

1900 to 1905 eleven cases have been operated on in Dr. Lilienthal's service at Mount Sinai Hospital. The cases included amputation of the breast, radical operation for umbilical hernia, suprapubic prostatectomy, partial excision of cancer or pharynx, and gastroenterostomy. Of these eleven cases the wounds healed satisfactorily in ten. The only case that died was a gastroenterostomy with a button in a cancer case. Death was due to peritonitis. We can but agree with the conclusions arrived at by Phillips after the study of a large number of cases. We should operate: 1. For malignant disease. 2. Large abdominal tumors. 3. Cosmetic operations, if the general condition is good. 4. Emergency operations, even under the most unfavorable conditions.

8. Gangrene of Skin. Furuncle, Carbuncle.—Griesinger figures that inflammatory gangrenous processes develop in 10 per cent. of all diabetic cases. The ages vary from twenty-two to eighty years. Forty per cent. occur between fifty and sixty years. The most common lesions are furunculosis and carbuncle. As the mild forms of diabetes occur chiefly in middle age, so we also find most of the cases of furuncle and carbuncle at that time of life. As a rule the urine contains only a moderate amount of sugar, and not much attention had been paid to the diet. The development of these lesions shows that there are serious errors in the body metabolism, and they should act as warnings of the storm to come. According to Grossman there is no case on record in which diabetes was cured after carbuncles had developed. The prognosis of gangrene of the skin *per se* is not bad; healing is often spontaneous. But the ultimate prognosis is bad, because only too often the gangrene of the skin is but the forerunner of more serious lesions. The necrosis of the skin generally occurs in the lower extremity. It begins either as a bluish red discoloration or as a blister. It may be caused by a scratch, by the scraping or cutting of a corn, or by any slight trauma, or even by exposure to cold. The gangrene is usually preceded by local numbness, cold, or pain. The treatment of furunculosis and of grangrene of the skin is chiefly dietetic. Some recommend mild antiseptic washes. Carbuncles generally develop on the dorsum. They should be treated by early and free incisions through the deep fascia. During convalescence the patient should be dieted. Of seventy-five large carbuncles reported from Gersuny's clinic five died of sepsis after operation. The earlier the incisions are made the less likely is sepsis to develop.

9. Mal Perforant.—It was formerly believed that every ulcus perforans was on a diabetic basis. It is found almost exclusively among men between forty and sixty years. In most of the cases the diabetes had not been recognized before the ulcer developed. In about 25 per cent. of the cases there were some symptoms of tabes. But, as Grossman points out, we often see pseudo-tabes in diabetics. The site of the ulcer is at one of the three points of pressure on the sole of the foot, *i.e.* the head of the first or the fifth metatarsus, or the heel. There is regularly a preexisting callus at the point of perforation. The prognosis is good. If we see an ulcer in this location which has a tendency to bleed, to become infected or gangrenous, especially if there is redness or edema of the leg, we must strongly suspect diabetes. The ulcer can generally be made to heal with stimulating dressings. In one case Gersuny excised the ulcer together with the head of the metatarsus with good result.

10. Abscesses.—As is well known, the diabetic is very prone to develop abscesses. In addition to the lowered vitality produced by the circulation of an abnormal amount of sugar, the presence of arteriosclerosis, and nerve degeneration, must also be taken into account. All these are contributory factors in the production of the various trophic lesions which affect the diabetic. The sugar directly lowers the vitality of the tissues, and, by producing chronic vascular and nerve lesions, it still more adversely affects the body economy. One of the commonest, as well as one of the most fatal, forms of abscess is the ischiorectal. A few years ago the writer had a case of this kind, which after free incision improved for several days and then went into coma. A prominent surgeon, who was asked to see the patient, remarked that he had never seen a case of this kind end in recovery. However, we recently had a successful case in Dr. Lilienthal's service. And last winter the writer was fortunate enough to save a far advanced case, and the patient is still alive, though suffering from a severe diabetes. As these patients stand suppurative processes very badly, the rule should be very early and very free incision.

11. Dry Gangrene and Wet Gangrene.—The three principal factors at work in causing gangrene are: (1) alcohol, (2) arterial changes, (3) bacteria. Alcohol acts by lessening tissue resistance, weakening the heart's action, and by predisposing to arteriosclerosis. The severity of the arteriosclerosis and the virulence of the bacteria are the great determining factors. We have seen above how the arteriosclerosis plays its rôle. The idiopathic or dry gangrene is largely due to the changes in the arteries and veins; the altered metabolism plays but a predisposing rôle. By the introduction of bacteria from without the dry gangrene is converted into an inflammatory or moist gangrene. How often this happens is shown by the fact that we see many more cases of moist gangrene than we do of dry gangrene. The comparative rarity of gangrene in women is less striking, if we recollect how much less frequent arteriosclerosis and alcoholism are in women than in men.

The following tables are from Grossman:

Character of Gangrene	Females.	Drinkers	Arterio-sclerosis.	Latent Diabetes	Total.
Ulcerations	4	3	8	0	24
Mal perforant	1	6	6	13	25
Dry gangrene	10	7	27	22	75
Wet gangrene	13	8	13	37	72
Total	28	24	54	82	185

DIABETIC GANGRENE

	Giron.	Mayer	Grossman.	Total.
Female	23 = 18.69%	10 = 7.86%	39 = 17.41%	72
Male	100 = 81.31%	46 = 82.14%	185 = 82.59%	331
Total	123	56	224	

In the overwhelming majority of the cases the lower extremity is the seat of the gangrene, just as the lower extremity is the favorite seat of the arterial changes. As Lilienthal says, "necrosis due to arterial obliteration is commonest in structures of little vascularity, such as tendon and fascia, while it is uncommon in very vascular tissues, such as mucous membrane. Fingers and toes being supplied by a terminal circulation, and being composed almost entirely of skin, bone, and tendinous structures, are especially liable to the disorder. The tension in the tissues which is caused by even a slight degree of infection will not infrequently so impair the circulation that necrosis occurs."

Dry gangrene cannot be attributed to outside causes. In a large percentage of the cases there are

marked arterial changes. The diseased vessels must be considered the predisposing cause, to which is added an exciting cause such as a tight shoe, exposure to cold, overexertion in walking, etc. As the result of one of these exciting causes the circulation, which had been poor enough owing to the arteriosclerosis, becomes completely cut off and gangrene results.

In wet gangrene there is always the added element of infection from without. A cellulitis is thus superimposed upon the gangrene. We have seen how the presence of sugar in the tissues predisposes to this infection. Once it has taken place we are further handicapped in combating it by the compromised arterial and venous systems and by the faulty metabolism. With varying rapidity the process is progressive. The infection spreads along the cellular planes between the muscles and tendons and along the lymphatics. The deeper tissues also become gangrenous and phlegmons, which endanger life, result.

12. Treatment of Gangrene.—Haidenhain gives three conditions under which spontaneous gangrene may occur: (1) A deficient supply of normal blood (senile); (2) a normal supply of abnormal blood (noma); (3) a deficient supply of abnormal blood (diabetic). At the very outset of the gangrene everything possible should be done to improve the local circulation. The patient should be in the recumbent position, the limb should be elevated and external heat applied. At times massage may be of use. Our aim should always be to keep the gangrene dry, and if it becomes moist to transform the moist gangrene into a dry gangrene. To bring this about dry antiseptic dressings and powders are employed; wet dressings of all kinds should be avoided. Antidiabetic diet will often aid in limiting the gangrene, especially if the patient has not had the benefit of diet for a long time. This is particularly true of the wet gangrene. In the dry form the general condition is usually much better, because the patient has been careful with his diet; accordingly, we cannot expect to influence the gangrene in these cases to any great extent by diet. As long as the gangrene remains dry, *i.e.* free from infection, no operation should be done until a line of demarcation forms. Limitation of the gangrene will be aided by elevation of the limb and dry dressings. Even when the line of demarcation is well established no operation should be done unless there is infection. With the expectant treatment one toe or several toes will gradually fall off, and leave a granulating wound which will often heal with little or no assistance. If there is infection, we try to limit it and bring about a condition of dry gangrene. To accomplish this blebs are opened as soon as they form, necrotic skin is cut away, a phlegmon is freely incised, the limb is elevated and covered with a dry dressing. The patient in the meantime is carefully dieted and everything done to improve the general condition. The urine is frequently examined not only for sugar but also for acetone, diacetic acid, and for the amount of ammonia excreted. Often we find improvement in the local condition go hand in hand with improvement in the condition of the urine. And we have seen above how important it is to limit acidity as well as the excretion of ammonia before proceeding to operation. If in spite of treatment fever persists and the phlegmon progresses, we must operate even without a line of demarcation. If there is no fever, which means that there is no infection, the waiting period will usually be from one to three weeks. During this time water should be given freely, also bicarbonate of soda; and, according to the suggestion of Rudisch, atropine in large doses together with codeine. Infection, when it takes place, is always from without. If, in spite of local and constitutional treatment, the infection is progressive, an amputation must be done to save life. We are then confronted by the vexed question of the site of amputation. The point of election will depend on (1) the condition of the arteries, (2) the extent of the phlegmon. According to Gerster, "if the popliteal pulse is felt, an amputation below the knee is admissible. In case of doubt, however, the higher amputation deserves the preference." Lilienthal advises against amputation at the knee, because there is so much tendinous tissue and so little muscle there that necrosis is very apt to appear in the stump. He suggests making all flaps of skin and muscle. Gussenbauer advises that the condition of the arteries should be carefully investigated on both sides. If the pulse is distinctly present in both tibial arteries, as well as in the dorsalis pedis, he claims that the removal of the diseased parts will suffice. But he adds that this rule has exceptions. He further states that if there is popliteal pulsation and none lower down, an amputation should be done below the knee, provided the gangrene has not spread beyond the dorsum of the foot and that the leg is free from phlebitis and lymphangitis. Where the phlegmonous process is rapidly progressive all are agreed that a high amputation must be done. As a rule operations on the toes or on the foot are insufficient if there is any infection. Haidenhaim's rules still hold good: (1) If there is extension of the process to the dorsum or palmar aspect of the foot the amputation should be made above the condyles of the femur; (2) amputation below the knee is frequently accompanied by gangrene of the flaps and jeopardizes the patient's life; (3) high amputation is indicated when the gangrene is progressive, although there may be no rise in temperature.

The statistics of G. B. Smith, Haidenhain, Kuster, and Smith and Durham, all go to show that where the gangrene affects more than three toes a high amputation gives the best results. We have referred above to the choice of anesthetic and to the preparation for and general technique of operations on diabetics. In amputations the Esmarch constrictor should not be used; digital compression of the femoral or external iliac should be employed instead. Long flaps are apt to become gangrenous; the flaps should be short and should consist of skin and muscle. No sutures should be used; the wound should either be left open or approximated in part or entirely with strips of Z. O. plaster. Drainage should be free. The result will usually depend on three factors: (1) The severity of the diabetes; (2) the condition of the heart; (3) the extent of the phlegmon.

Grossman collected 58 cases of amputation for diabetic gangrene: 22 leg amputations with 9 deaths; 21 thigh amputations with 9 deaths; 7 Gritti knee amputations with 4 deaths; 2 Pirogoff amputations with 1 death; 1 Chopart amputation with 0 death; 3 toe exarticulations with 0 death; 1 toe amputation with 0 death; 1 finger amputation with 0 death. Total, 58 amputations with 23 deaths, a mortality of 39.6 per cent. This mortality may at first sight seem high, but we must remember that in cases of extensive gangrene the mortality without operation is fearful. Phillips reported from St. Bartholomew's Hospital, from 1884 to 1899, eleven cases of gangrene not operated on and they all died. The chief causes of death after operation are coma, sepsis, and cardiac failure.

TABLE OF OPERATIONS.*

Name and Date.	Age and Sex.	Lesion.	Duration of Present Illness.	Treatment.	Result.	Remarks.
S. S., 1901..	M., 52	Gangrene of foot.....	3 weeks.....	1. Pirogoff amput. 2. Amp lower third thigh.	+ 3 days after 2d operation.	1½% sugar, albumin, hyaline and granular casts.
M. D., 1901..	M., 44	Gangrene of toes.....	2 weeks.....	Amput. of toes.....	+ 6 hours.	1% sugar, albumin, gran. casts
R. W., 1901..	F., 50	Strangulated umbilical hernia	3 days.....	Radical operation...	Cured.	1%–2% sugar.
S. L., 1901...	M., 56	Luetic orchitis mistaken for T. b. c.	7 weeks.....	Orchidectomy.....	Cured.	2% to 5% sugar.
B. A., 1902...	M., 58	Gangrene of foot, lymphangitis of leg..	2 weeks.....	Amput. middle thigh.....	+ coma 24 hrs.	3% sugar, acetone, albumin, hyalo-granular casts.
I. G., 1902...	M.	9 weeks before admission toe amput. Gangrene spread to foot.	9 weeks.....	Amput. middle of thigh.....	+ 4 days after operation.	4%–5% sugar, acetone.
J. S., 1902...	M., 59	Gangrene of foot.....	8 days.....	Amput. middle of leg.....	+ 3 days.....	2%–3½% sugar
M. M., 1903..	M., 56	Carcinoma of pancreas.....	4 months...	Exploratory laparotomy and drainage.	Unimproved....	1%–3% sugar.
S. S., 1903 ..	M., 63	Prostatic hypertrophy.....	Several years.	Suprapubic prostatectomy...	Cured	For several years had had up to 1½% sugar.
W. C., 1903...	M., 57	Prostatic hypertrophy	Several years	Suprapubic prostatectomy	Cured	Sugar present for several years
M. A. S., 1903	M., 60	Cellulitis of foot	4 weeks	Incision and drainage.....	Cured...	1% sugar, acetone, trace of albumin.
S. G., 1903...	F., 54	Gangrene of foot....	8 days	Amput. lower third thigh. ..	Cured	Up to 4% sugar, acetone.
M. S., 1903...	M., 55	Gangrene of foot.....	2 weeks.....	1. Incision foot, amput. toe 2. Amput middle thigh....	Cured..	1% –5% sugar, acetone, diacetic acid.
I. B., 1903...	F., 62	Gangrene of foot.....	1 week.....	Amput. lower third thigh....	+ Coma, 8 days	2%–3% sugar, acetone, diacetic acid, albumin.
N. R., 1904...	M., 58	Lipoma neck.....	2 years	Excision of tumor	Cured.	1%–2% sugar, trace albumin.
N. T., 1904...	M., 48	Cancer of pharynx	5 years..	Partial excision	Improved. ...	7/10% sugar, acetone, diacetic acid
B. H., 1904 ..	F., 56	Fibroma breast.	6 weeks.....	Excision of tumor.....	Cured.	2%–3% sugar, diacetic acid.
S. K., 1904....	M., 53	Cancer stomach.....	Several mos...	Post-gastroenterostomy with button.	+ 3 days peritonitis	2½% sugar.
M. K., 1904 ..	M., 55	Stones in gall-bladder and duct	5 weeks. ..	Cholecystectomy and choledochotomy.	Cured	1%–1½% sugar, trace albumin
S. S., 1904. ..	F., 53	Gangrene finger.....	2 weeks	Amput. finger	Slow healing	1% sugar, acetone, diacetic acid.
R. R., 1905...	F., 32	Scirrhus breast.....		Radic. amput. breast....	Slow healing.	6/10% sugar, acetone, diacetic acid.
H. B., 1905...	M., 52	Gangrene of foot. ..	3 weeks ..	Amput. middle thigh. ..	Slow healing	1½%–2% sugar.
J. E., 1905 ..	F., 54	1 Gangrene toe. 2. Secondary gangrene foot.	2 weeks. ..	1. Amput. small toe. 2. Amp lower third thigh.	1st op. Nov. 27 2d op. Dec. 21 + Coma, Dec. 25, 1905	2%–7% sugar, acetone, diacetic acid, albumin, hyaline and granular casts.

*The operations were performed by Drs. H. Lilienthal, C. A. Elsberg and J. Wiener

Conclusions. 1. We must distinguish between diseases due to diabetes, and those that occur independently of the disease.

2. All necessary operations for diseases not due to diabetes should be performed just as in ordinary patients.

3. The abnormal products (acetone, diacetic acid, β-oxybutyric acid, lactic acid) which circulate in the blood in diabetes do harm, (*a*) by injuring the tissues and making them prone to infection; (*b*) by acting as contributing factors in producing premature arteriosclerotic changes.

4. Arteriosclerosis plays a very important rôle in producing diabetic gangrene.

5. There are two kinds of diabetic gangrene: (*a*) that caused by changes in the arteries and veins; (*b*) that caused by the effect of virulent bacteria on weakened tissues.

6. We should always endeavor to transform wet gangrene into dry gangrene.

7. If more than three toes are affected, especially if there is any cellulitis, a high amputation is generally indicated.

8. If the infection is progressive a high amputation should be done.

9. If in doubt about the site of amputation, a high amputation will give the best results.

10. If more than one gram of ammonia is excreted in twenty-four hours, operation had better be postponed until by careful diet the amount of ammonia is considerably reduced.

11. The prognosis does not depend on the percentage of glucose in the urine but on the degree of acid intoxication.

12. A strict meat diet will reduce the amount of sugar, but it will often bring on fatal coma by increasing acidity.

13. Sodium bicarbonate given before and after operation can do no harm and may do good.

14. Ether and chloroform should be avoided as much as possible.

15. All operations on diabetics should be performed as simply and as rapidly as possible.

RARE FORMS OF CHORIOIDITIS:

ONE VARIETY DUE TO GENERAL MALARIAL INFECTION AND ONE TO AUTOINTOXICATION FROM INTESTINAL PTOMAINS.*

BY CHARLES STEDMAN BULL, A.M., M.D.,

NEW YORK.

THESE forms of chorioiditis are not often met with by the ophthalmic surgeon. In posterior uveitis, due to either of the above causes, the disease must be regarded as caused by the microorganisms conveyed to the eye from elsewhere within the body by the blood current, and these organisms must perforce be arrested and adhere to the walls of the vessels before they can cause damage; such arrest or stoppage being commonly promoted by the microorganisms being contained in coagula or particles of broken-down tissue, or aggregated in colonies.

The first variety of chorioiditis referred to, that due to general *malarial* infection, is a rare ocular complication. Severe forms of malaria, and the accompanying profound anemia thereby induced, met with in tropical countries and in certain regions of our own Southwestern States, must be regarded as the more or less frequent cause of chorioiditis. Malarial inflammation of the entire uveal tract, including chorioid, ciliary body and iris, not infrequently occurs in patients suffering from severe malarial poisoning, like jungle fever, and these attacks of uveitis may come on years after the original exposure to the fever. Some of the characteristics of these attacks are their periodicity and their tendency to relapse. Their course is most tedious, though the patients usually recover their vision almost completely.

In malarial attacks certain eye symptoms may form part of the attack, and have even been known to be a substitute for the general attack. Supraorbital neuralgia, ptosis, spasm of accommodation, amblyopia, and even complete amaurosis, without ophthalmoscopic findings, have been observed, not only in severe atacks of malarial fever, but even in latent malaria. Why, then, may not chorioiditis develop as one of the symptoms of profound malarial saturation of the whole organism?

It has been my experience in the past to meet with a goodly number of cases of severe intraocular lesions occurring in profoundly malarial patients, and in most of these a distinct type of chorioiditis was present. As is generally known, after the malarial poisoning has lasted a long time, a series of complications often occurs, such as diffuse vitreous opacities and multiple retinal hemorrhages, but I have not found in literature any mention of a distinct type of chorioiditis, consisting of small patches of yellowish exudation, fairly circular in form, but with little elevation above the surface, which occur all over the fundus, and do not tend to coalesce. These are distinct from the pigmentary deposits not infrequently found in the fundus after malaria of long standing, which are undoubtedly due to pigment emboli, the result of gradually developing melanemia. This type of chorioiditis is very often accompanied by a general uveitis with fixed punctate opacities of the vitreous, and the patches of chorioidal exudation may be entirely hidden by these opacities, and only become visible when the vitreous has cleared up. These yellow patches are very different from the shining white spots in the retina left after retinal hemorrhages.

As corroborative evidence of the occurrence of these patches of exudation, at autopsies on malarial patients, changes have been found in the chorioid which were not recognized before death, consisting of small inflammatory foci with thromboses of the chorioidal vessels. The vitreous opacities are often absent throughout the entire course of the disease.

One of the striking features of these cases is the marked disproportion which exists between the degree of the acuity of vision and the actual amount of chorioidal disease present. The whole fundus may show an extensive inflammatory process, and yet the central vision may be very good, provided no vitreous complications are present.

These cases are very chronic in their course, and show but little sign of improvement under the usual treatment of chorioiditis. It is not until quinine has been administered in steadily increasing doses, accompanied by arsenic and iron, that the chorioid begins to clear up, and the vitreous opacities disappear. Yet the prognosis is good if the cause is recognized and the disease is properly treated, and the ultimate vision is normal, or nearly so.

The second variety of chorioiditis, above referred to, is still rarer than the malarial, and, if possible, still more interesting. For some years Elschnig has been making a special study of gastrointestinal autointoxication as a factor in the development of ocular affections. He regards it as especially important as a cause of ophthalmoplegia interna, and more rarely of paralysis of the external ocular muscles and of affections of the optic nerve. He has also found intestinal intoxication to be a cause of diseases of the cornea and sclerotic, and of affections of the uveal tract, especially of recurring iritis and of insidious iridocyclitis.

Following on somewhat different lines of investigation, Grover discovered that, in a large number of cases of eye disease, for which he could discover no primary cause, the test for indican in the feces and urine resulted strongly positive. In all of these cases there were evidences of digestive disturbance. As indican is an indication of putrefactive processes in the intestines, Grover assumes that its presence in these cases indicates that poisons from the intestines are circulating in the body and affecting all the organs in the body, and these disturbances are visible in the eye, and attract attention. The relation of chorioiditis to autointoxication is very inter-

*Read before the New York Academy of Medicine, November 1, 1906.

esting. A careful search of ophthalmic literature reveals very few well-authenticated cases of lesions of the deeper tissues of the eye due to autointoxication. Intestinal poisoning from ptomains represents a sort of transition to acute infectious diseases. The toxic products of the disassimilation of food vary greatly in character, and some of them have a specific action on the eye. While we are all familiar with the commoner general symptoms of intestinal intoxication, the localized ocular symptoms are much less evident. Conjunctival injection, paralysis of accommodation of the levator palpebræ, and of the external muscles of the eyes, are not infrequent symptoms. In many of these cases vision is not impaired, but a number of cases of amblyopia without ophthalmoscopic findings have been reported, for which no satisfactory explanation has been offered. These visual disturbances are doubtless primarily due to putrefactive changes occurring in the animal tissues.

During the past few years I have seen quite a number of cases of autointoxication, accompanied by marked lesions of the deep tissues of the eye, notably a chorioiditis of an unusual type. They all presented the usual ocular symptoms of conjunctival injection, paralysis of accommodation, and mydriasis, but in addition the fundus presented an unusual picture. Scattered all over the fundus of both eyes were patches of yellowish-white exudation in the chorioid, of varying size and shape, very flat, with scarcely any elevation above the general level of the fundus. Some were in the stage of efflorescence and others in the period of retrogression and absorption. The older patches were surrounded by a reddish margin, but no masses of pigment could be seen anywhere in the fundus, and no retinal or chorioidal hemorrhages. The vitreous remained entirely clear, and the vision was but slightly affected, showing that the retina was but little, if at all, involved in the process. There was no limitation of the field and no scotoma, and no disturbance of the color perception.

The patches of exudation in the chorioid presented a very different appearance from that of chorioiditis areolaris disseminata, or from that of the chorioretinitis associated with general constitutional syphilis.

Occasionally I have seen faint peripheral striæ of opacity in the lens of both eyes, but these did not extend, and eventually entirely disappeared. These cases all showed a marked cutaneous eruption of the pemphigoid type, some of the bullæ on the abdomen and inner surface of the thighs being quite large. The contents of these bullæ have frequently been examined by Elsching, Valude, and others, and a diplococcus has been isolated from the bullæ and injected into the veins of rabbits, and invariably caused death. The diplococcus removed from the blood of the poisoned rabbit was identified with that removed from the pemphigus bullæ, and when injected intravenously into a pig produced a pustular eruption.

The *prognosis* as to vision in these cases is good, especially if the patient gradually recovers from the general toxic infection.

As regards the *treatment* of these cases, before the administration of any drugs specifically directed towards the chorioiditis, it is at first wise to introduce such dietetic and therapeutic measures as seem best indicated to regulate the digestive tract, for such measures will essentially improve or cure the chorioiditis, after failure of all other forms of treatment.

The treatment should later consist of the administration of iron, arsenic, and strychnia, the two latter drugs being given separately, so that the dose of each may be increased or diminished according to indications. Under this treatment, the patches of exudation lose their yellow color, and become paler, slowly diminish in size and become less clearly defined, the red ring rapidly fading away. At the periphery of the fundus the patches disappear entirely, while those in the vicinity of the posterior pole of the eye are more or less permanent, though in several patients, after a lapse of three years, they were distinguished with difficulty.

THE TREATMENT OF TYPHOID FEVER AND PNEUMONIA.

By LEONARD WEBER, M.D.,

NEW YORK.

Symposiums on typhoid fever, pneumonia, etc., we have had in our societies, and continue to have. They are often good to attend, and the newcomers in our ranks will always be glad to listen to what clinicians of experience may have to say to them. When the discussion is ended, there is a mass of individual testimony as to pathology and therapy, and the hearer—particularly the younger disciple of the healing art—can make his choice of what he thinks best for diagnosis and treatment in his next case.

A summing up and final agreement upon the best mode of treatment which ought to hold good for a year or more or, at all events, until the next symposium goes over the same ground again, would be serviceable, I opine, and be heartily welcomed by many members, so far as I have been able to ascertain.

It is a matter of common experience that every active practitioner not only watches and nurses a case of pneumonia or typhoid fever, but really treats it, hoping by such treatment to insure the favorable outcome which he trusts or expects will take place anyway. For this very reason I may be allowed to state briefly what mode of treatment has served me well in

Typhoid Fever.—Far be it from me to belittle the laboratory—etiological—diagnosis of typhoid fever, yet I have always held and taught that a case of this disease can be diagnosed by its well-known syndrome, and be under safe care and management before, and often many days before, the agglutination test confirms our diagnosis. Now, when we witness an epidemic of typhoid or examine a sporadic typhoid case brought into the hospital ward in the second week of the fever, there will be no difficulty in diagnosing the case correctly, but it is in some of the milder sporadic cases of typhoid and typhoid-like diseases that the difficulty of exact diagnosis presents itself. I am ready to confess that it is mainly through cases in private practice that I have learned that typhoid fever is not a uniform disease, and that there are not only different degrees of real typhoid, but also some typhoid-like diseases which it may be difficult and sometimes even impossible to distinguish and classify properly. We have known for quite a while that the *Bacillus coli* may become virulent and produce a sort of typhoid; we have learned in recent years of the paratyphoid bacillus giving rise to somewhat of a true typhoid. Last July I had a case of scarlatina in a lad of nineteen, followed by typhoid fever fifteen days after the initial sore throat and rash, and running a typical course. In September last I observed two cases of subacute enterocolitis which

had been clinically diagnosed as typhoid, but the agglutination test remaining negative as often as it was made, the diagnosis could be properly corrected. Four weeks ago I was called to see a patient who had eaten badly cooked or spoiled liver sausage early in January of this year, and within a few hours after ingesting the stuff he was seized with nausea and vertigo, but not vomiting. He took one ounce of castor oil early the next morning, with good effect, felt better for a day or two, and then went into a low state of fever lasting three weeks, and presenting the usual clinical symptoms of mild typhoid, but the agglutination tests remaining negative, the diagnosis of typhoid fever could be replaced by the proper one of enterocolitis.

In all cases of the kind mentioned, and others of a similar nature, the agglutination tests are indeed of great help, but if the physician comes to believe that one or two early tests are adequate to settle the diagnosis *pro* or *con*, further experience will soon tell him that this is not so, and that the agglutination tests do not always show up when we think they ought to.

Whether the Eberth bacillus, the paratyphoid bacillus, or the colon bacillus will be found to be the etiological factor in typhoid fever need not make a bit of difference in the treatment.

Ever since I read of the splendid results which Erb and Binz had in treating typhoid fever with a single full dose daily of quinine, in the German field army during the Franco-German war of 1870, I have followed pretty much the same method. The results which those authors had at the time were far better in their cases than in those which were treated by coal-tar antipyretics, or by the expectant plan, that is, by doing nothing for the patient until something serious demands action, and when that action not infrequently does not avail.

In the initial stage of typhoid fever almost every physician orders calomel or some other purgative to clear the bowels. It is done not only in this, but in every acute infection; surgeons do the same, and it is well, for by it offensive material will be removed from the intestines; but as to calomel or any other so-called germicide doing much good by sweeping out a lot of typhoid bacilli and thereby diminishing the virulence of the infection, that is truly a forlorn hope. For at the stage of infiltration of the intestinal follicles, the blood already swarms more or less with typhoid bacilli, not only so, but it is very probable that the bacilli enter the blood current before any intestinal localization has taken place. A moderate dose of sulphate of magnesia would answer our purpose as well, I think, here as it does in abdominal surgery cases. This having been done, I order a daily evening dose of quinine muriate, fifteen grains to an adult, one-half of that to a patient under fourteen years of age, to be given in one dose or in two or three divided doses, and to be continued daily until the chart shows defervescence. In cases in which the temperature reaches its maximum toward the end of the first week, and all circumstances point to a severe infection, I have ordered 7½ grains at four, six, and eight P.M., with singularly good, and never with harmful results. To be sure, a case of idiosyncrasy will be met with once in a great while, where quinine will not be borne by the patient.

In such a case, tubbing, after Brand, is probably the best thing we can do, for the resports from our city hospitals, where the Brand method is practised, show us many more convalescents from typhoid fever than they had before, by the expectant treatment and good nursing alone. In private practice, however, two competent nurses are needed for giving the Brand baths in the proper way, and careful supervision on the part of the doctor is essential. Where these requirements cannot be fulfilled a modified course of hydrotherapy, in the manner so ably described and explained by Dr. Baruch in his book on hydrotherapy, may be confidently applied.

In regard to the diet appropriate for the typhoid patient, the last word can be said, I think. Peptonized milk and farinaceous foods, and pure water *ad libitum*, until the disease is at an end, and then soft diet for a week or two longer. I have seen mischief follow the introduction of solid food in some cases of typhoid with more or less pronounced intestinal localization, and I hold that no conscientious practitioner ought to take it upon himself to go contrary to the rules for diet laid down by Osler and other experienced clinicians.

Pneumonia is a self-limited disease, so Austin Flint said and wrote many years ago. If so shrewd an observer and physician as Austin Flint looked rather kindly on lobar pneumonia as it ran its course in his days—and how many cases may he not have seen before he uttered his dictum—he must have had very good reason for it, but pneumonia as we have had it with us the last twenty-five years is an alarming and frequently fatal disease, and always a source of considerable anxiety to the attending physician.

It seems to me that the classical chill and rapid filling up and consolidation of an entire lobe of the lung are not so much the fashion as in years gone by, and resolution by lysis is at least as frequent as, if not more so, than by crisis. Not infrequently a part of a second lobe is affected before the first has cleared up, and further, we meet with cases in which we have two or more days of anxious waiting before the pneumonic process starting from the center reaches the periphery and permits us to be certain in our diagnosis. Again, we have had the grippe with us since 1889, and those who have seen much of grippe pneumonia will know how tedious such cases are and what a long wait it is before they recover.

In treating pneumonia I have put my faith in quinine, digitalis, and the cold, wet compress applied around the affected side from sternum to spine, and frequently changed; eventually heart excitants, such as hypodermics of camphorated oil and stimulants; and in so doing I have been but seldom disappointed as to the outcome of the disease.

As soon as the diagnosis is fairly well established, a daily evening dose of 7½ or 15 grains of quinine muriate, according to the age of the patient, is given in one or in divided doses, then the cold-wet compress is snugly applied, covered with oil-silk and flannel, and frequently changed. By this application the pleuritic stitch and dyspnea will soon be relieved and a hypodermic of morphine is generally avoided. Delirium and insomnia I find best relieved by five grains or more of Dover's powder, and occasional enemas of tepid water; a good large room and a plentiful supply of fresh air day and night are essential for the welfare of the patient. To *take the pulse frequently*, carefully count and prove its strength, is very important indeed. At the first sign of cardiac weakness quinine is discontinued, and a freshly-made infusion of English digitalis leaves (½ dram to six ounces), ½ ounce every two or three hours, administered until cardiac action has improved. When we cannot afford to wait for the sometimes slow action of the infusion of digitalis we have now a rapidly acting preparation in Cloetta's soluble digitoxin, a prepared solution of which may be given by mouth or hypodermatically. This is reliable and prompt in its effect. For quickly

stimulating a failing heart I prefer hypodermics of camphorated oil in one-half dram doses every half of one hour, to combinations of strychnine and nitroglycerin, though I would not object to their use if another man should wish to give them the preference of camphorated oil.

Barring the rapid consolidation of an entire lung or the greater part thereof, in which a copious venesection is indicated to save the heart and the patient's life, it is not the overloading of the right heart in the average case of pneumonia which threatens to paralyze the organ, but rather the acute and severe intoxication of the system by the pneumonic toxins; I do believe that in quinine, given in fairly large doses once in twenty-four hours, we have a remedy which really counteracts such toxins and thereby probably diminishes the severity of the infection.

Grippe pneumonia, on the other hand, is a different proposition altogether: it may come slow, it may come fast, it almost creeps over various portions of one or both lungs, it lingers, and when it finally gets well convalescence is slow. I know of no remedy which could be called a remedy here, and therefore careful nursing and judicious symptomatic treatment are our main reliance.

PUS TUBES IN THE MALE.

TREATMENT BY INJECTIONS THROUGH THE VAS DEFERENS.

By WM. T. BELFIELD, M.D.,

CHICAGO,

ASSOCIATE PROFESSOR OF SURGERY (GENITOURINARY), RUSH MEDICAL COLLEGE.

Pus infection of the seminal tube, including the vesicle, appears to be quite as frequent as pus infection of the Fallopian tube in the female. It is, however, not so often recognized, for its usual symptoms—pyuria, frequent and painful urination, and partial or complete retention of urine—are usually referred to the bladder and prostate, and the patient therefore treated for cystitis and prostatitis.

The infections of the seminal tubes are three—the gonococcus, pyogenic bacteria, and the tubercle bacillus; as the last induces suppuration only with the aid of the pyogenic bacteria, it will be omitted from consideration as a cause of pus tubes in the male. The pus infections of the seminal tube are extensions from the deep urethra; they result from (1) gonorrhea, (2) stricture, (3) prostatic concretions, and other causes of prostatic suppuration in middle-aged and elderly men.

Invasion of the seminal vesicle by the gonococcus induces the symptom complex usually considered indicative of prostatic abscess—frequent and painful urination, complete retention of urine terminated by a sudden discharge of pus, often an ounce or two, into the urethra. These phenomena are usually due to abscess formation in the seminal vesicles, as emphasized by Lloyd[1] fifteen years ago; or in the utricle,[2] as shown by myself twelve years ago.

A typical gonorrheal abscess of the utricle was recently observed by Dr. L. E. Schmidt and myself; the symptoms were those usually ascribed to prostatic abscess, but the fluctuating swelling was greatest midway between the lateral borders. With the fingernail the abscess was incised from the rectum; after the escape of perhaps an ounce of pus, the lateral lobes and median groove were distinctly felt.

Stricture of the bulbous urethra favors pus infection, which, beginning in the poorly nourished tissues, extends backward through the deep urethra into the seminal duct and vesicle, at times even to the epididymis. As the infection may extend forward in the urethra also, and thus produce a pus discharge from the meatus, the entire clinical picture simulates a gonorrhea, and by physicians who neglect to examine the pus with the microscope it is often so called—to the disgust and indignation of the innocent patient.

The nongonorrheal infections of the seminal tube in men over forty years of age are, like everything else causing bladder symptoms in these patients, labeled "prostatic hypertrophy"; and they do indeed cause the same symptoms, including even complete retention of urine. These are the cases of alleged prostatic enlargement that were benefited by vasectomy, when that operation was popular. The prevalent rage for prostatectomy causes the unfortunate subject of vesiculitis to be accused of harboring an enlarged prostate and to be condemned to prostatectomy. A typical example of this common ailment of elderly men was a patient seventy-two years old, seen with Dr. Henrotin nearly three years ago. He suffered from the usual symptoms of "cystitis" for several weeks, culminating in complete retention of urine. The left seminal vesicle was distended and tender, the prostate merely swollen; incision of the abscess was declined, but the pus traversed the vas, causing an abscess of the epididymis. When this was opened and the vesicle thereby drained, the bladder function was completely restored and the patient has had no urinary trouble since. A case practically the duplicate of this was seen with Drs. Billings and Phillips about the same time. By all the canons of the general surgeon, both these old men should have been subjected to prostatectomy—though their prostates were in no wise to blame, unless indeed because of the irritating presence of prostatic concretions, universally found in men past middle age.

The pus infections (nongonorrheal) of the seminal tube, especially in elderly men, constitute an almost wholly neglected field; the obvious explanation is that already indicated—namely, the practical identity of symptoms with those caused by infections of the prostate and bladder, from which pus tubes have not been clinically distinguished. One whose attention has never been directed to this topic will be surprised to discover the number of cases treated for cystitis, prostatitis, and "prostatic enlargement," whose lesions are really pus infections of the seminal tube and vesicle. The differential diagnosis is by no means difficult; the usual mistake in diagnosis arises from the habitual failure to recognize pus tubes as the cause of pyuria, frequent and painful urination, and partial or complete retention of urine.

Gonorrheal infection of the seminal vesicle, on the other hand, has been frequently identified, since Lloyd[3] called attention to its occurrence and advised incision of the suppurating vesicle with a long-bladed knife through the perineum. About the same time Dittel,[4] the father of perineal prostatectomy, used the incision which he had devised to attack the prostate, for exposing and incising gonorrheal abscesses of the seminal vesicle. Dittel's operation was later modified and developed by Fuller,[5] who has reported 74 cases in which he has attacked the vesicle for suppuration and other lesions through this extensive perineal dissection.

The Dittel-Fuller operation is admittedly severe and bloody, entailing risks and requiring weeks of confinement to hospital. It seems justified, if at all, only in cases of perivesiculitis, since the immediate

relief sometimes demanded by pyovesiculosis is furnished far more simply and safely by incision with a cautery knife from the rectum. (The cautery is preferable to the knife for this incision, because it avoids bleeding, averts infection, and prevents premature closure of the wound.) But a much simpler and more effectual medication of the seminal tube and vesicle is secured by the operation that I have devised and practised,[6] which can be done in the office. It consists essentially in opening the vas, stitching the cut edges to the skin, and injecting through a curved hypodermic needle any chosen solution into the proximal vas; this liquid traverses the vas and ampulla and enters the seminal vesicle. By digital massage from the rectum, the injected liquid can be expressed into the urethra if desired. Through the fistula daily injections of the vesicle can be made so long as seems necessary, after which the fistula is easily closed. Complete transverse section of the vas may safely be made, if preferred, since anastomosis of the cut ends and restoration of the lumen is easily accomplished. For injections through the vas the solutions commonly employed in the urethra are used; but the first injections should not exceed thirty to sixty minims, lest spermatic colic and retention of urine be provoked. Both of these effects I witnessed in my earlier work; the spasmodic contraction of the vesicle seems to cause spasm of the bladder sphincter—an item of both clinical and physiological interest. The influence of the seminal ducts upon the bladder and its sphincter suggests an explanation of the cause and cure of "irritability" of the bladder in some cases.

THE PREAPPENDICITIS STATE.

By JOHN G. SHELDON, M.D.,

KANSAS CITY, MO.

It is generally believed by the laity and the medical profession, and it is taught by our modern textbooks, that acute appendicitis is sudden in its onset, and that it develops without previous symptoms suggestive of the disease. (The well known varieties of chronic appendicitis that may be subject to acute exacerbations are, of course, not considered in the foregoing.) Recently, there seems reason to believe that our views regarding the onset of acute appendicitis will undergo a change. Some clinical observers no longer hold that acute appendicitis should be looked upon as a primary and very acute affection, but consider it, at least in some instances, as the result of a chronic process that has paved the way for its occurrence. Mumford and Stone, after considering appendicitis from all standpoints, state that "it seems as though we were often justified in regarding appendicitis as a chronic disease clinically, and subject to acute exacerbations."

A limited operative and clinical experience, associated with the ordinary work of a general practitioner, has led me to believe that acute appendicitis rarely occurs without previous, more or less definite, symptoms having been complained of for three months to one year. This conclusion has resulted from the obtaining of definite histories of acute appendicitis cases operated upon; and, by examining, and keeping in touch with the developments in patients complaining of obscure and very mild gastrointestinal symptoms. An accurate history of the symptoms of the patients whom I have operated upon for primary attacks of acute appendicitis during the last three years, has shown in almost every instance that, while the patients invariably date the history of their illness from the beginning of the acute attack, they have suffered from slight and occasional abdominal pain, and many times constipation and flatulency, for a period of several months before the acute involvement of the appendix began. These so-called preappendicitis symptoms have been found to be so often present in cases of acute appendicitis that it seems probable to me that their occurrence is the rule and not the exception. Their existence is easily overlooked. They are mild and of long standing, while the acute attack is so definite and so serious that it completely overshadows the patient's previous complaints.

It is a common experience in general practice to be consulted by patients, who have been apparently well in every respect, complaining of unusual, mild, and diffuse pain in the abdomen, with perhaps a loss of appetite and moderate constipation. A careful examination of these patients revealed, in most instances, no cause for the symptoms. A cathartic generally relieved them. When, however, these symptoms had existed for a period of three to six months, during which time the symptoms would disappear for a week or ten days at a time, examination revealed in most instances a very slight tenderness over the appendix. Repeated examinations showed that this tenderness was not constant. The symptoms and findings did not warrant a diagnosis of chronic appendicitis, consequently no diagnosis was made, but the patients were kept under observation. Eighteen such patients developed acute and serious appendicitis within three months to one year after the first complaint of the mild and indefinite abdominal symptoms. Five others gradually developed chronic appendicitis for which operation was done. Three patients are still under observation, who supposably have been in the preappendicitis state for four months, seven months, and nine months respectively.

If it is true that acute appendicitis is many times preceded by the so-called preappendicitis state, the symptoms of this period, according to the cases observed, would be intermittent diffuse, but slight abdominal pain in all of them; moderate constipation in approximately three-fourths of them; noticeable abdominal distention in a few; and slight, but not constant, tenderness over the appendix on deep pressure. The frequent finding of these symptoms in a patient who later developed acute appendicitis, together with the history of the frequent occurrence of such symptoms preceding a primary acute appendicitis, suggested the existence of a preappendicitis state.

The practical importance of recognizing the preappendicitis state, if such exists with any degree of constancy, bears directly on the present mortality of acute appendicitis. We are perhaps not justified in advising operation for patients in the preappendicitis state; but we should warn them of the probability of suffering from an acute attack of appendicitis in order that they may seek competent advise at the beginning of the acute symptoms. Such advise may seem unnecessary when we consider all that has been said regarding the diagnosis and treatment of appendicitis; but the present mortality of acute appendicitis should be reduced. Entirely too many cases are brought for operation after perforation and local or general peritonitis have occurred.

MEDICAL RECORD.

New York, May 4, 1907.

THE FUNCTION OF ALKALOIDS IN PLANT LIFE.

THE study of the vegetable alkaloids has been prosecuted so diligently and so successfully in recent years that the chemical structure of fifty of these substances is now known in detail, and twenty of the structural formulas have been confirmed by artificial synthesis of the corresponding alkaloids. The origin of these bodies and the part played by them in the life of the plant are discussed by Aimé Pictet in a paper recently read before the Swiss chemical society of Neuchatel.

The sources of alkaloids, he says, and the processes by which they are formed in vegetable cells, have long been matters of discussion. The old theory of Heckel that the alkaloid is the first result of assimilation, and represents a stage in the formation of albuminoids has been shown to be erroneous. Lartz and Clautrian have proved that the true alkaloids, such as quinine, atropine, cocaine, morphine, caffeine, solanine, and betaine, cannot serve as plant food, that the quantity of these alkaloids in the seed increases, instead of decreasing, during germination, and that a diminution of the quantity of alkaloid is never accompanied by a corresponding increase in albuminoids. So that we are led to regard the alkaloids, not as products of assimilation, but as results of the partial decomposition of more complex substances. Certain groups of atoms, or parts of the complex molecule, appear to be more stable than others, and these groups resist disintegration and appear as alkaloids. The alkaloids, being nitrogenous decomposition products resulting from vegetable metabolism, are analogous to the urea, uric acid, and bile pigments of animals. But the plant cannot, like the animal, promptly get rid of the waste products because it has no eliminating organs. Some plants, no doubt, find means of destroying their alkaloids so rapidly and completely that they do not appear to produce any. In other plants this process, if it occurs at all, is slow and imperfect, so that the organism is compelled to retain its excreta for a time and to confine them to certain cells and tissues where they cannot injuriously affect the general life of the plant. Hence the characteristic localization of alkaloids in such peripheral parts as roots and fruits, where, as they are poisonous to many animals, they incidentally serve as a protection to the plant. This power of localization of alkaloids is, therefore, of advantage in the struggle for existence, and it is most strongly developed in the most highly organized plants.

Such localization, however, is not the only means by which the plant can protect itself against the injurious effects of substances which it can neither eliminate nor destroy. In the animal organism poisons, whether resulting from metabolism or introduced from without, are not usually excreted unaltered, but undergo various changes which make them less poisonous or more soluble, and therefore easier of elimination. The change may be simple oxidation, combination with other substances, or both. That plants, which possess greater powers of synthesis than animals, adopt similar methods, and that the alkaloids extracted from plants represent the poisonous products of excretion not in their original form, but in combination, appears probable for the following reasons: In most vegetable alkaloids the molecule is composed of two distinct parts, a nitrogenous nucleus and one or more groups of very different chemical character. Again, when a plant yields several alkaloids, which is usually the case, all have the same nucleus, and differ only in the number and character of the secondary groups. Finally, the plant, like the animal, makes its nitrogenous excreta more complex, thereby neutralizing the atomic groups which have a poisonous action on protoplasm.

Caffeine, theobromine, and theophylline, the alkaloids of coffee, cacao, and tea, as well as many others, have an origin identical with that of their animal analogues, such as uric acid, from which artificial caffeine is now made. They may be regarded as decomposition products of nuclein. The alkaloids of the choline group have a similar origin. Choline, a nonpoisonous alkaloid, is found in toadstools and hops, and also in pickled herrings and human corpses. In the animal tissues it arises from the saponification of one of its compounds, lecithin. Vegetable choline and its immediate derivatives, muscarine (the poison of toadstools) and sinapine (found in white mustard seed), undoubtedly owe their existence to a similar reaction. We must, therefore, regard all these alkaloids as decomposition products of vegetable lecithin. Nicotine, atropine, cocaine, and strychnine may be derived directly from albuminoids, which appear also to be the indirect sources of the alkaloids of opium, cinchona, and some others.

TROPICAL NEURASTHENIA.

THE experiences of many of the Americans who have gone to the Philippines illustrate only too well the fact that prolonged sojourn in tropical regions is usually attended, in white persons coming from the temperate latitudes, by a great depreciation in the powers of mental and physical application, often going on to such a degree as to render imperative a speedy return to more accustomed climatic conditions. Strange to say, writers on tropical life do not appear to have given this form of neurasthenia the attention it deserves: at least there have been but few contributions to the literature of the subject. Among the more important writings on this matter are those of Major Charles E. Woodruff, who speaks of the condition as being so common an occurrence as to merit the special term of tropical exhaustion, and states that in addition to its more patent manifestations it re-

duces the powers of resistance to every disease as, it lessens the natural immunity.

A careful study on the subject by Louis H. Fales appears in the *American Journal of the Medical Sciences,* April, 1907. He states that from his Philippines experience he believes that nearly all American women and a large proportion of the men who have been in the islands for a year or more suffer at least to some extent from nerve exhaustion. A conservative estimate, he says, would be that 50 per cent. of the women and 30 per cent. of the men are affected to such an extent that they are in a state of semi-invalidism. They lose the power of mental concentration, suffer from loss of memory, become easily fatigued, and are inefficient as workers. The women become nervous, irritable, and anemic, lose weight, suffer with neuralgia and insomnia, and almost invariably are troubled by menstrual irregularities. Fales further expresses the opinion that, directly and indirectly, tropical neurasthenia incapacitates more white men in the Philippines than all other causes combined, and seems to be the main difficulty in the process of acclimatization.

In general the nerve exhaustion of the tropics does not differ greatly from the neurasthenia seen in this country, but menstrual derangements such as menorrhagia, metrorrhagia, and dysmenorrhea are unduly frequent in the women patients. Vasomotor symptoms such as angioneurotic edema and pemphigus, localized sweatings, etc., are also common. Fortunately, the condition responds to treatment more promptly than ordinary neurasthenia, and change of climate is usually effective. The greater prevalence of the condition in the tropics naturally leads to inquiry regarding the special etiological factors that may exist in such regions. No doubt the lack of willingness or ability to conform to the habits of the native in regard to hours of work, the noonday *siesta,* and other time-wasting but health-conserving customs of the country plays a large part in the downfall of the energetic white man in hot countries, and there must be added to this the predisposition to nervous exhaustion attending certain common tropical diseases such as dengue and amebic dysentery. Fales expresses himself rather conservatively in speaking of the alcohol question and in this connection quotes Woodruff's figures, which appear to show that the use of alcohol is not especially detrimental in the tropics. He suggests that the moderate use of alcohol may serve to prevent infection by intestinal parasites by stimulating the action of the gastric secretions and by a direct antiseptic action on the parasites themselves.

Rather more importance is accorded to Woodruff's theory of overstimulation by the excessive quantity of actinic rays present in tropical sunshine, which has already been discussed in these columns, and concerning which the author says that there can be no doubt that this effect of the violet and ultraviolet rays plays an important part in the etiology of tropical nerve exhaustion. He lays most stress, however, on the high temperature and high humidity that prevail in the Philippines, as the result of which there is an almost constant abnormal dilatation of the arterioles of the skin. This leads to an anemia of the internal organs, of course including the central nervous system, with the result of nervous malnutrition and derangement. An ingenious portion of the author's argument is that in which he points out that, owing to the smaller relative skin surface of large men, these require more active cutaneous circulation in order to effect a sufficient cooling of the blood, and that in consequence they must be particularly prone to evidences of nervous anemia and cardiac overactivity, a supposition which is borne out by the facts.

From these considerations it is evident that the proportion of persons for whom a prolonged stay in the tropics is likely to be possible without more or less risk must be a rather small one. Woodruff has stated that the best age is from twenty to thirty or thirty-five years, and that no man over fifty-five should go there for more than a short visit. Fales believes that the tropics should be avoided especially by blondes, large men with great musculature, those with tuberculous tendencies, those having gastric or intestinal disorders, neurasthenics of all sorts, women, children, and old men. The requirements of tropical hygiene involve avoidance of the actinic rays as much as possible, including the use of sun shades and clothing properly selected as to color and material, and refraining from overwork, especially from exertion during the middle of the day. Five hours is to be considered a fair day's work. In regard to diet, it is a mistake to believe that dwellers in the tropics need little meat. The greatest care is also necessary in preparing the food in order to avoid intestinal infection, and green vegetables and unboiled water must be shunned.

From all of this it appears that only such persons as are physically and mentally fitted for it should go to the Philippines, and that while there they should use common sense in conforming to local customs regarding work, rest, and clothing, and what might be termed uncommon sense in the selection of their food and in the supervision of the details of its preparation. These conditions complied with, the dangers are perhaps not so very great, but it is evident that infractions of the rules of hygiene are even more likely to be fraught with serious consequences in the tropics than in the temperate latitudes.

PYELITIS IN CHILDHOOD.

Among the uncommon and unfortunately often unsuspected conditions found in children is an inflammation of the renal pelvis. This may be due to the ingestion of certain medicaments or to mechanical or toxic irritants. In older children it may also be due to a faulty diet leading to an excess of uric acid or urates in the urine. In exceptional cases the presence of certain parasites such as echinococcus, strongylus, or distomum, may lead to the disease on account of the deposit of eggs or embryos in the urinary passages. Extreme degrees of phymosis, hypospadias, or pressure exerted on the bladder or ureter may lead to infection of the mucous membrane of the renal pelvis by producing decomposition of the urine. A pyelitis may occur during the later

stages of one of the infectious diseases, particularly scarlatina or variola. Tubercle bacilli which have found their way into the urine may also lead to a tuberculous infection of the pelvis, and the gonococcus may likewise produce a specific local inflammation by direct extension from a vulvovaginitis of this character. In every case the disease is ushered in by a chill, followed by a moderate elevation of temperature unless urinary stasis is present, when the fever will be much higher. When there is profuse suppuration present, localized pain is also complained of, and this may be referred to the bladder, the meatus, the perineum, or the thigh. There may also be a severe dysuria. The most important point in the diagnosis is to be gained, however, from the uranalysis. The total quantity of urine may be unaffected or slightly increased, but the pus which is invariably present gives the fluid a cloudy appearance, which increases on standing. The sediment on microscopical examination will be found to be mainly pus, together with the characteristic cells from the pelvis of the kidney. Albumin is present in varying degree depending on the amount of blood or pus.

The prognosis is fortunately good in most cases if the condition is not neglected. In acute cases in which the condition is due to medicinal or even mechanical irritants, healing takes place within from one to four weeks. When the pyelitis is due to urinary decomposition recovery is likewise prompt if the cause of the latter can be removed, but when a growth is present the outlook is less favorable, and a fatal result may be determined by uremic poisoning. A pyelitis due to one of the infectious diseases is apt to run a protracted course, and even when recovery takes place recurrences are frequent. In treating this disease, Monti (*Allgemeine Wiener Medizinal-Zeitung*, 1907, No. 1) calls attention to the importance in all acute cases of absolute rest in bed and a milk diet, and this must be continued until the urine is entirely normal. As soon as a recurrence is noted this same regime must again be instituted. Diuretic measures are also indicated, and much good results from the use of warm baths lasting from fifteen to twenty minutes, of either plain or sea water, mud, or the water of some natural thermal springs. When an irritating medicament is at fault, its administration must be stopped and the excretion favored by various means. Local measures, including bladder irrigation, are required in appropriate cases, and the urinary antiseptics may also be given, though with care, as they are very apt to cause considerable disturbance.

The Scrotal Tongue.

This is the rather inelegant name applied to a peculiar condition of the tongue which is occasionally met with, and in which the dorsal surface of the organ is the site of a number of symmetrical furrows which give it a shriveled appearance similar to that seen in the skin of the scrotum. It is necessary, as shown by Chambardel in a recent article in the *Archives Générales de Médecine*, No. 44, 1906, that this condition be carefully distinguished from the pathological furrowing of the tongue which is associated with carcinoma, syphilis, tuberculosis, and similar lesions, and the physiological furrows which are found in many persons on either side of the median line. From both of these the deformity of the tongue in quetsion may be distinguished by the symmetry and depth of the furrows which extend over the entire dorsal surface of the organ and around on the sides. An hypertrophy of the labial papilla is frequently seen, but this has no apparent connection with the other condition. The tongue thus afflicted is of a bright red color, and is usually broad and flat. The mouth itself may be perfectly normal in other respects, except that there is very apt to be an enlargement of the salivary glands, and their secretion is increased. In isolated instances an hypertrophy of the lacrymal glands has also been observed. Although a tongue of this kind may not give rise to any symptoms, it offers a favorable field for the development of leucoplakia, glossitis, ulcers, and a variety of other local processes. We know practically nothing of the etiology of this condition, and the histology is likewise uncertain. The only direction in which an insight into the true nature of the lesion may be gained would seem to be from the standpoint of embryology or comparative anatomy.

Meningeal Irritation from Spinal Anesthesia.

The not infrequent reports of serious complications attending the employment of cocaine for purposes of medullary anesthesia must naturally dampen the enthusiasm with which this procedure has been advocated by many surgeons. It is of undoubted value in many instances as a substitute for ether or chloroform, but from the number of accidents which occur as the result of its administration it would appear that the indications for its use have not thus far been completely formulated. Among sequelæ of spinal cocainization which are less frequently observed are evidences of meningeal irritation. A few instances have been reported, and to these another is now added by Schick (*Wiener klinisch-therapeutische Wochenschrift*, No. 46, 1906), who undertook to do a curettage for an incomplete abortion, in a very nervous patient, by the aid of medullary narcosis. The injection was made in the usual manner and the patient then placed in the Trendelenburg position for a few minutes. The operation was successfully done, and the woman made an apparently good recovery. On the third day, however, she was seized with a severe headache, which was accompanied by an increasing rigidity of the neck muscles. The pulse rate then dropped to from 48 to 54 beats per minute. There were no psychic disturbances and no ocular symptoms. Vomiting was also present, and this, with the other symptoms, persisted for about eight days, when a gradual improvement took place. These phenomena, which were most marked, gave every evidence of being due to a meningitis, and yet the latter could with considerable certainty be excluded. It is possible that severe nervous disturbances of this kind may depend, to a large extent at least, on some peculiar idiosyncrasy regarding the drug manifested by nervous persons. If so, patients of this class would seem to present a particular contraindication against the employment of the procedure in question. In omitting the elevated pelvic position, the writer thinks it might be possible to limit the field of action of the anesthetic, and this is applicable to most of the gynecological operations. To the impartial observer the occurrence of such serious sequelæ constitutes, however, a drawback to the use of the spinal anesthesia which is hardly counterbalanced by its assumed advantages.

Decision Regarding Abortionists.

The Appellate Division of the Supreme Court on April 19 wrote an opinion which will prove of great assistance in securing convictions of professional abortionists. Some time ago the Medical Society of the County of New York, through its counsel, caused the arrest of a woman who had placed in certain New York City newspapers an advertisement of unequivocal import. She was charged with maintaining a public nuisance in violation of Sections 385 and 387 of the Penal Code, inasmuch as she received into her house pregnant women and used instruments upon them to procure unlawful abortions. The defendant was tried in the Court of Special Sessions and sentenced to one year in the penitentiary and to pay a fine of $500. The case was appealed on the ground that no crime under Section 385 of the code was committed, and that no adjudicated case has been found in which it has been held that the maintaining of a house for the purpose of practising the vocation of an abortionist constitutes a nuisance. The Superior Court, however, affirmed the conviction, stating that it is a nuisance for a person by public advertisement to invite and receive a class of the public to his premises for the purpose of violating the laws of the State, as was done in this case. It is further stated that the offense of abortion is one thing, but that of maintaining premises open to the public for the purpose of consummating that crime is another and separate offense against the peace and good order of the State. It is an inducement to moral laxity and to crime, and is within the letter and spirit of the sections of the Penal Code under consideration. The counsel of the County Medical Society state that this is the first case of its kind recorded either in this country or in England, and that now that this precedent has been established it will be much easier to secure convictions for illegal abortion, as there will no longer be the necessity of laying elaborate traps to catch a defendant *flagrante delictu*.

Hysterical Fever.

The existence of a rise of temperature depending on an hysterical basis has often been questioned, and yet cases undoubtedly occur in which no other cause than a nervous one can be found to account for the fever. An instance of this kind is referred to by Comby in the *Bulletin Médical*, 1906, No. 36, as having taken place in a girl of thirteen who was rather weakly, and had been the subject five years previously of an attack of what was called subacute peritonitis, which was probably of a tuberculous nature. The symptoms improved, but several years later she became afflicted with a tremor of the arms following a mild attack of influenza, which was characterized by a relatively slight rise of temperature. After this the course of the temperature presented several points of interest; although never over 100° F. in the morning, it would rise to 107° F. in the evening. Notwithstanding this enormously high temperature in the evening, there was apparently no marked effect on the patient's general condition, and after the fever subsided the child spent the rest of the night quietly. The general character of the case led to the thought that an hysterical basis was the underlying factor in the production of the high fever, and the patient was treated with wet packs and psychical influences, which finally resulted in complete recovery. Such instances have occasionally been reported in the literature, and we may assume that, in children particularly, where no organic disease can be found to account for a continued high temperature, the rise in temperature is of purely hysterical origin.

Tuberculous Meningitis without Tubercles.

In a recent issue of the *Lancet* (April 13) reference is made to an interesting case recently reported by Sireday and Tinel, who call attention to the fact that, although tubercles of various forms anatomically characterize tuberculosis, they are in some cases absent, especially when the disease is located in the central nervous system. Thus meningitis may be occasioned by a diffuse bacillary infiltration or even tuberculous toxins. The authors referred to report the case of a boy admitted to hospital in a comatose condition. He had been sick for two weeks with headache and vomiting, and gradually became comatose. Rigidity of the neck, photophobia, wasting, mydriasis, irregularity of the pulse, the meningeal streak, Kernig's sign, and lesions at the apices of the lungs left no doubt as to the diagnosis of tuberculous meningitis. Lumbar puncture showed marked lymphocytosis of the cerebrospinal fluid and some polynuclear cells. The case ran the ordinary course and death occurred after an illness of almost eight weeks. At the necropsy the most minute examination failed to show any tubercles on the meninges or in the cerebral cortex. To the naked eye the changes consisted in an intense congestion of the nervous centers, of which the vessels were much distended. The meninges had lost their transparency and at several points showed a slight thickening with a milky tint, little pronounced. The meninges could be raised without tearing the adjacent cerebral substance. The subarachnoid space and the ventricles contained a notable quantity of liquid. The lungs showed diffuse tuberculous lesions, large granulations of the size of a lentil confluent in some places, disseminated in others. Microscopic examinations revealed numerous tubercle bacilli in these granulations. To the naked eye the kidneys showed nothing abnormal, but the microscope disclosed little tuberculous nodules. Microscopic examination of the meninges showed a diffuse leucocytic infiltration without any tuberculous granulations. In some places the cells were agglomerated into little nodules, but nowhere was there a definite tubercle. The case exactly corresponded to the type described by Delille as "diffuse leucocytic infiltration, predominantly perivascular, and with tendency to nodules." In no preparations could giant cells or caseous degeneration be seen—nothing suggestive of formation of tubercles. But large numbers of tubercle bacilli were disseminated wherever there was leucocytic infiltration of the membranes. They were especially grouped around the blood-vessels, forming in certain places little agglomerations without modification in the form or grouping of the neighboring cells.

Abscess of the Liver.—Excellent results may be obtained in liver abscess cases (solitary abscesses), which drain for a long time, by applying a Bier cup over the superficial opening once a day for five minutes. One must be especially cautious in these cases not to increase the vacuum too rapidly, as rupture of the vessels in the liver might easily ensue and cause serious damage.—*American Journal of Surgery*.

News of the Week.

Civil Service Examinations for the State and County Service.—The State Civil Service Commission will hold examinations May 25, 1907, for the following positions: Coroner's physician, Albany county, $600; night superintendent, Erie County Hospital, $420 and maintenance. The last day for filing applications for these positions is May 18. Full information and application forms may be obtained by addressing Charles S. Fowler, Chief Examiner of the Commission, at Albany.

Joint Conference of Illinois State Board of Health and Officers of Medical Societies of the State of Illinois.—A joint conference was held April 24, 1906, at the Great Northern Hotel, Chicago. During the meeting the following committees submitted reports, which were freely discussed and adopted: Committee on Reciprocity; Committee on Medical Legislation in Illinois; Committee on Relation of State Board of Health to Local Boards of Health; Committee on Examination of Candidates and Methods Pursued in Connection with the Administration of the Medical Practice Act in the Case of Unlicensed Practitioners; Committee to Promote Cooperation Between the State Medical Societies and the State Board of Health, and also a Committee on Cooperation Between the Different Schools of Medicine. One of the committees in its report urged the holding of such a conference yearly, and it is believed that this suggestion will be carried out.

For More Park Milk Booths.—A committee acting in behalf of several charitable organizations interested especially in the care of the children of the poor, has requested the Board of Park Commissioners to make application to the Board of Estimate and Apportionment for an emergency appropriation of $8,000 for the purpose of erecting eleven additional milk booths in the parks. If the booths are provided Mr. Nathan Straus has agreed to bear the cost of furnishing pasteurized milk for distribution, and of the necessary attendance.

Health Conditions on the Isthmus.—According to the report for the month of March, of Col. Gorgas, chief sanitary officer of the Canal Zone, the conditions on the Isthmus are now so satisfactory that much improvement can hardly be expected. Since last August the number of sick among the employees has steadily declined, until it is now 19.40 men per 1,000, as against 33.72 in August. Among 4,600 American white employees there were only two deaths from disease during the month of March. Among 1,200 American women and children living in Canal Commission quarters there were no deaths, and very little sickness of any kind. The negro employees continue to show the highest mortality, and the American whites the smallest.

Alvarenga Prize.—The next award of this prize which consists of the income for one year, amounting to $180, of the fund left for this purpose by the late Señor Alvarenga, will be made on July 4, 1907, provided that an essay deemed worthy of the prize shall have been offered.

Italian Prizes.—Among the subjects for which prizes are offered by the Reale Instituto Lombardo, are the following: For the Cagnola prize for 1908, the so-called nuclei of origin and termination of the cranial nerves; for the Secco Comneno prize for 1907, a discovery relating to the virus of rabies; for 1911, on the physiological action of high-frequency currents. For the present year the prize awards of the Reale Instituto Lombardo include a Cagnola prize of £100 and medal of the value of £20 to Dr. Augusto Moschini of Pavia, for his essay on the pathology of the suprarenal capsules; a prize of £80 to Dr. Guido Sala of Pavia, and awards of £20 to Professor Domenico Lo Monaco and G. Pitò of Rome for essays on the anatomy of the visual centers of higher vertebrates under the Fossati foundation.

Dr. Charles H. Peck, the Senior Attending Surgeon to the French Hospital of this city, has recently received from the French Government, through the Minister of Public Instruction and Fine Arts, the decoration of Officier de l'Instruction Publique.

Dr. Theodore H. Weisenburg has been elected neurologist to the Philadelphia Hospital and consultant to the Insane Department, and also professor of neuropathology and assistant professor of neurology in the Medico-Chirurgical College, in succession to the late Dr. Wm. Pickett.

Dr. John B. Deaver has been elected consulting surgeon to the Philadelphia Hospital in succession to the late Dr. John H. Brinton.

Resignation of Dr. Mettler.—Dr. L. Harrison Mettler has resigned from the faculty of the Chicago Clinical School.

A New Clinical Society.—The members of the medical staff of the New York Throat, Nose, and Lung Hospital have organized a society known as the Clinical Society of the Hospital. Members and ex-members of the staff are eligible for membership. The officers for the first year are as follows: *President*, Dr. E. A. Miller; *Vice-President*, Dr. S. Goldstein; *Secretary*, Dr. Chas. F. Walter; *Treasurer*, Dr. M. C. Tracy. The next meeting will be held at the hospital, 229 and 231 East Fifty-seventh street, on Wednesday, May 1, 1907. The program for the evening embraces the presentation of patients, specimens, and instruments, and the reading of a paper on tinnitus aurium by Dr. C. F. Walter.

Memorial Hospital Plans.—A committee of the Iroquois Memorial Hospital Association has presented a plan for a memorial emergency hospital in the downtown district of Chicago, to the President of the Cook County Board. It is proposed by the committee to lease the ground at 43 and 45 La Salle street, at an annual rental of $5,000, and to erect thereon a three-story building to cost about $30,000. The Hospital Association is willing to pay for the building, but it asks the county to pay for the lease of the land.

An International Congress of First Aid to the Injured.—Under this title an international congress is being planned for, to be held in Frankfurt a. M., Germany, in the spring of 1908, and to be devoted to the subjects of first aid and life saving in factories, on railroads, in agricultural pursuits, in mines, at sea, etc. The methods and appliances in use in different countries are to be exhibited and discussed. The chairman of the committee of arrangements is Oberbürgermeister Adickes of Frankfurt.

Board of Food and Drug Inspection.—Secretary Wilson has created a Board of Food and Drug Inspection, whose duty it shall be to administer the national pure food law. The board consists of Dr. Harvey W. Wiley, chairman; Dr. Frederick L. Dunlap, and George R. McCabe.

Hospital Conference.—At the recent meeting of the Hospital Conference of the City of New York the subject of dispensary management was discussed. In view of the constantly growing number of persons requiring dispensary treatment it was decided to make a statement to the Mayor and to the heads of hospitals regarding the necessity for increased dispensary facilities.

The Presbyterian Hospital will receive between $120,000 and $150,000 by the will of the late Peter Cumming, founder of the Broadway Savings Institution.

New Public Bath for the Bronx.—Plans have been filed for a new two-story free public bath to be erected at the southeast corner of Elton avenue and 156th street. It is to be of brick, with trimmings of ornamental stone, and will front 67 1-2 feet on both avenue and street and have a depth of 58 feet. It is to cost $140,000.

Hospital Saturday and Sunday Association.—The distributing committee of the Hospital Saturday and Sunday Association met last week to distribute the undesignated fund of the collection of 1906. The total collection was reported as $103,110, of which $1,555 was derived from the offer of Mr. and Mrs. James Speyer to duplicate all gifts after $100,000 had been collected. Of the total, $14,610.88 was designated by the donors to particular institutions, and $4,492.12 was reserved for future expenses, leaving the sum of $84,000 for distribution. The allotment was made on a basis of the free work done by each institution. The Montefiore Home and Hospital and Mount Sinai Hospital got the largest awards, $8,400 each. St. Luke's, Roosevelt, the Lebanon, and German Hospitals each received amounts exceeding $4,000, and thirty-three other institutions received smaller apportionments.

Death from X-Rays.—The death of Wolfram C. Fuchs, which occurred in Chicago last week, makes at least the fifth instance in which *x*-ray workers have succumbed to lesions caused by continual exposure to the rays. Mr. Fuchs about three years ago suffered serious burns of both hands, which necessitated his retirement from active work, but in spite of this and of repeated amputations, the condition progressed, and the lesions finally involved the trunk and internal organs.

Suicide in Japan.—According to recently published statistics, the practice of self-destruction is steadily increasing in Japan, and during the year 1904 6,200 men and 3,900 women ended their own lives. This is an increase over the figures for the year 1890 of 14.5 per cent. for the men and 16 per cent. for the women. Hanging and drowning are the two methods most often used.

Museum for Haeckel.—The municipality of Jena has given a plot of land, on which a philogenetic museum will be established in honor of Professor Ernst Heinrich Haeckel.

Medical Inspection of Immigrants.—In reference to the editorial in a recent issue of the MEDICAL RECORD on the relation of immigration to the prevalence of insanity, Dr. Thomas W. Salmon informs us that Surgeon George W. Stoner of the Public Health and Marine Hospital Service is in charge of the medical inspection of immigrants at Ellis Island, and that Dr. Salmon is one of several officers of this service assigned to duty there.

Scurvy in Russia.—Scurvy has become very prevalent in the famine districts of Russia. Official reports show that in the last two weeks of March 1,055 cases were discovered in the province of Ufa alone, and up to April 25 11,000 cases in all had been reported in the same province.

Typhoid Fever in Warsaw.—An outbreak of typhoid fever has occurred among the thousands of political prisoners confined in the overcrowded prisons of Warsaw, and the disease has become epidemic throughout the city.

The Syrian Protestant College of Beirut, Syria, in which Dr. George E. Post is professor of surgery, has received from Mrs. Russell Sage the sum of $75,000 for the erection of an American hospital.

International Congress of Physiotherapy.—The twelfth international convention of those interested in this branch of therapeutics will be held in Rome, October 13 to 16, 1907.

Harlem and Fordham Hospitals.—The new buildings of these two hospitals are ready for occupancy. The new Harlem Hospital occupies nearly half a city block on Lenox avenue, between 136th and 137th streets, fronting on the former. Besides the main building, which is a five-story brick and stone structure, there are separate buildings for the ambulance station and power house. The new Fordham Hospital main building, which, like the Harlem Hospital, is but a part of a system of contemplated structures, is five stories in height and is built of stone and brick. To the rear of the main building are the ambulance stables, laundries, and servants' quarters. Beside it to the west is a large four-story stone and brick building to be devoted to the nurses. The buildings are at the Southern boulevard and Crotona avenue.

Michigan State Board of Health.—Dr. Angus McLean of Detroit has been elected president of the State Board of Health, succeeding Dr. Victor C. Vaughan of Ann Arbor. Dr. F. W. Shumway was reelected secretary.

Bequests to Philadelphia Institutions.—In accordance with the terms of the will of the late Edward T. Dobbins of Philadelphia, the executors have distributed the following legacies: Scholarship in the Philadelphia College of Pharmacy, $25,000; Hospital of the Women's Medical College, $10,000; Christ's Church Hospital, $10,000; Burlington County Hospital, Mt. Holly, N. J., $5,000; Children's Hospital, $5,000; Home for Incurables, $5,000; Free Bed Women's Medical College, $5,000.

The Congress of American Physicians and Surgeons.—The seventh meeting of the Congress of American Physicians and Surgeons will be held in Washington, D. C., May 7, 8, and 9. The meetings of the congress will be held in the convention hall of the Arlington Hotel. The subject to be considered at the first session is "The Historical Development and Relative Value of Laboratory and Clinical Methods in Diagnosis." In the evening there will be the address of the President of the Congress, followed by a reception to him. On Wednesday the subject for discussion will be "The Comparative Value of the Medical and Surgical Treatment of the Immediate and Remote Results of Ulcer of the Stomach." On Thursday evening there will be the usual smoker.

American Society of Sanitary and Moral Prophylaxis.—At the meeting of this society held April 11, 1907, the following officers were elected for the ensuing year: *President*, Dr. Prince A. Morrow; *Vice-Presidents*, Dr. Stephen Smith, Prof. Edwin R. A. Seligman, and Mr. Francis Lynde Stetson; *Secretary*, Dr. Edward L. Keyes, Jr.; *Treasurer*, Dr. Smith Ely Jelliffe.

American Therapeutic Society.—The eighth annual meeting of this organization will be held in

Washington on May 4, 6, and 7, 1907, under the presidency of Dr. Robert Reyburn of Washington. The secretary is Dr. Noble P. Barnes of Washington.

American Laryngological Association.—The twenty-ninth annual congress of this association will be held in Washington on May 7, 8, and 9, 1907. The president of the society is Dr. Arthur W. de Roaldes of New Orleans, and the secretary is Dr. James E. Newcomb of this city.

American Medical Editors' Association.—The thirty-eighth annual meeting of this organization will be held at Atlantic City on Saturday, June 1, and Monday, June 3, 1907. The annual editors' banquet will be held at the Marlborough-Blenheim Hotel on the evening of June 3. The opening address by the president, Dr. James Evelyn Pilcher, will be on "The Future of Medical Journalism," and numerous other speakers will discuss the present conditions of medical journalism. The secretary is Dr. Joseph MacDonald, Jr., of this city.

The West Virginia State Medical Association will hold its annual meeting at Huntington on May 15 to 17, 1907. The officers for this year are: *President,* Wm. W. Golden, Elkins; *Vice-President,* V. T. Churchman, Charleston; *Secretary,* T. W. Moore, Huntington; *Treasurer,* T. L. Barber, Charleston.

South Carolina State Medical Association.—At the meeting of this society held in Bennetsville on April 18 officers were elected as follows: *President,* Dr. LeGrand Guerry, Columbia; *First Vice-President,* Dr. J. Adams Hayne, Greenville; *Second Vice-President,* Dr. Marsh, Edgefield; *Third Vice-President,* Dr. Mary R. Baker, Columbia; *Secretary,* Dr. Walter Cheyne, Sumter; *Treasurer,* Dr. C. P. Aimar, Charleston; *State Board of Health,* Dr. Robert Wilson, Charleston; Dr. Hall, Aiken; Dr. C. C. Gambrell, Abbeville; Dr. J. Adams Hayne, Greenville; Dr. W. J. Burdell, Lugoff; Dr. James Evans, Florence; Dr. C. F. Williams, Columbia.

St. Joseph Railway Surgeons.—At the annual meeting of the Society of Surgeons of the St. Joseph and Grand Island Railway, held in St. Joseph on April 18, officers were elected as follows: *President,* Dr. B. F. Hatch of Beattie, Kan.; *Vice-President,* Dr. G. A. Birdsall, Alexandria, Neb.; *Secretary and Treasurer,* Dr. R. A. Todd of St. Joseph.

Worcester North (Mass.) Medical Society.—The forty-ninth annual meeting of this society was held in Fitchburg on April 23. Officers as follows were elected: *President,* Dr. A. E. Mossman of Westminster; *Vice-President,* Dr. J. G. Henry of Winchenden; *Secretary,* Dr. Walter F. Sawyer of Fitchburg; *Treasurer,* Dr. E. R. Fiske of Fitchburg.

Georgia State Medical Association.—At the annual meeting of this society, held at Tybee on April 19, officers were elected as follows: *President,* Dr. M. A. Clark, Macon; *First Vice-President,* Dr. Ralph M. Thomson, Savannah; *Second Vice-President,* Dr. E. E. Murphy, Augusta. The 1908 meeting will be held in Fitzgerald.

Florida State Medical Association.—The election of officers at the annual meeting of this society, held in Tampa on April 18, resulted as follows: *President,* Dr. W. P. Lawrence of Tampa; *Vice-Presidents,* Drs. S. R. M. Kennedy of Pensacola, J. D. Love of Jacksonville, and W. H. Powell of Ocala; *Secretary,* Dr. J. D. Fernandez of Tampa.

Cole County (Mo.) Medical Association.—Officers as follows were elected by this society at the meeting held in Jefferson City on April 19: *President,* Dr. C. P. Hough; *Vice-President,* Dr. H. T. Leach; *Secretary,* Dr. Bedford; *Treasurer,* Dr. J. P. Porth.

Tolland County (Conn.) Medical Society.—At the one hundred and fifteenth annual meeting of this society, held in Rockville on April 16, officers were elected as follows: *President,* Dr. T. F. Rockwell, Rockville; *Vice-President,* Dr. Jas. Stretch, Stafford Springs; *Clerk,* Dr. E. P. Flint, Rockville.

Plymouth District (Mass.) Medical Society.—Officers were elected as follows at the annual meeting of this society, held in Brockton on April 17: *President,* Dr. F. G. Wheatley; *Vice-President,* Dr. Fred J. Ripley; *Secretary and Treasurer,* Dr. Alfred C. Smith.

Litchfield County (Conn.) Medical Society.—The forty-third annual meeting of this association was held at Winsted on April 24. Officers were elected as follows: *President,* Dr. G. D. Ferguson of Thomaston; *Vice-President,* Dr. I. L. Hamant of Norfolk; *Clerk,* Dr. S. G. Howd of Winsted.

Death of Mosetig-Moorhof.—Professor Albert von Mosetig-Moorhof, the Viennese surgeon, well known, among other things, for his method of treating bone cavities with an iodoform-paraffine filling, was accidentally drowned on April 26. He was subject to syncopal attacks due to arteriosclerosis, and while walking along the Danube is thought to have felt a seizure coming on. He was seen to stoop at the river's edge, apparently to wet a handkerchief in order to bathe his face, but lost his balance and was carried away by the swift current. He was sixty-nine years old.

Obituary Notes.—Dr. Junius F. Smith of Brookfield, Conn., died on April 22 of pneumonia at the age of forty-two years. He was a native of New Marlboro, Mass., and was graduated from the Long Island Hospital Medical College in 1890. He began to practise in Brookfield in the same year, and for some time before his death had been the medical examiner for the town. Last year he was elected Representative from Brookfield in the General Assembly and was a member on the Committee of Public Health and Safety.

Dr. Frank P. Webster of Norfolk, Va., died suddenly on April 25 of heart disease. He was fifty-four years of age.

Dr. W. B. Fletcher of Indianapolis died in Orlando, Fla., on April 25, after a long illness.

Dr. Charles D. Mattison of Minetto, Oswego, county, N. Y., died suddenly on April 22, at the age of thirty-five years. He received his medical degree from Johns Hopkins University.

Dr. I. D. Young of Bordentown, N. J., died on April 26 at the age of eighty-two years. He was born at Rockland, Del., and was graduated from the Pennsylvania Medical College of Philadelphia in 1848. A year later he began practice in Bordentown, where he had resided ever since. He was consulting surgeon to the Meyer Hospital at Trenton.

Dr. Winthrop Butler of Vineyard Haven, Mass., died on April 22 at the age of sixty-eight years. He was born in Tisbury and studied medicine with his uncle, Dr. S. W. Butler of Newport, R. I. He received his degree from the Harvard Medical School in 1866, and after practising for a time in Groveland, Mass., removed to Vineyard Haven, where he had since resided.

Dr. Herbert S. Olney of Detroit died on April 18 at Fresno, Cal., at the age of thirty years. He

was graduated from the medical department of the University of Michigan in 1901, and in 1903 began to practise in Detroit. A year ago he was forced to go West on account of ill health.

Dr. M. C. CRISTENSEN of Omaha, Neb., died on April 17 after an illness of several months. He was a native of Denmark and was graduated from the Omaha Medical College in 1892. He served as Alderman from 1900 to 1902.

Dr. ESROM A. DU CLOS of Flint Village, Mass., died on April 20 at the age of sixty-four years. He was born in Quebec and received his medical education in Bishop University and McGill University. He had practised in Flint Village for about four years.

Dr. FRANCIS E. CORBIN of Los Angeles, Cal., died suddenly on April 17. He was educated in the University of Michigan and the Michigan Medical College. After practising for a time in Lansing he removed to Los Angeles about eleven years ago.

Dr. GUSTAVE SCHOENBERG died at Philadelphia on April 20 at the age of eighty-one years. He was a native of Prussia, his ancestors being the Dukes of Schoenberg. He was graduated from the University of Berlin in 1848 and was engaged in medical practice in Berlin until 1860, when he came to the United States. In 1873 he went to Japan and in the following year he was made Surgeon-in-Chief to the Japanese Army. While in the Orient he went to Formosa, and he was one of the first white men to explore that country. He also visited many parts of China that up to that time had been closed to foreigners.

Dr. GEORGE W. SMITH died at Hollidaysburg, Pa., on April 22, at the age of seventy-three years. He was graduated from the medical department of the University of Pennsylvania in the class of 1863. He was for many years president of the Blair County Medical Society and for ten years president of the Hollidaysburg Board of Health.

Dr. ANDREW M. MILLS of Newark died suddenly on April 21 at the age of thirty-six years. He had lived in Newark all his life and had practised there since his graduation from the New York University Medical School in 1892. At the time of his death he was County Physician of Essex county.

Dr. REUBEN BIGELOW BURTON of this city died on April 22, after a brief illness. He was born in Chester, Vt., June 15, 1827. He was graduated from Union College and subsequently from Albany Medical College in 1855. He practised in Chester, Vt., but came to settle permanently in New York in February, 1860. He was in active practice up to the week before his death.

(From Our Special Correspondent.

SALICYLATES—EXTENSIVE VOLVULUS—ALCOHOL, A NEW DECLARATION—KING'S HONOR TO HIS SURGEONS—COLLEGE OF PHYSICIANS—ITEMS—OBITUARIES.

LONDON, April 12, 1907.

THE administration of salicylates was the subject of a paper at the Hunterian Society by Dr. David Lees, who holds these preparations to be among our most certain remedies. He said, indeed, that sodium salicylate was as directly antagonistic to acute rheumatism as mercury to syphilis or quinine to malaria. I have met men who set quite as high a value on this drug. On the other hand, I have discussed it with others who hold it to be much less certain, and in some cases dangerous; they have recounted to me in fact such cases, in some of which they thought it hastened death. I have therefore been interested in what Dr. Lees said, and will summarize his views. First of all, he said it is too often given in too small doses, on account of the unpleasant symptoms which it sometimes produces, and on account of the general opinion that it is a cardiac depressant. In children he made light of the disagreeable symptoms, except vomiting, and this he said is arrested by omitting two or three doses. He always combined it with full doses of bicarbonate of soda. Potassium salts were depressants of the heart, but he considered sodium salts as distinctly cardiac stimulants and likely to diminish the tendency to dilatation in acute rheumatism. He increased the dose every day, or on alternate days, up to a maximum of 450 grains in twenty-four hours for adults. He had given a boy of fifteen 600 grains in twenty-four hours, and 500 grains for six days a week for three weeks. It was not necessary to omit it during pericarditis. If the salicylate were given without the bicarbonate a sort of acid intoxication might occur resembling diabetic coma. In chorea, Dr. Lees said, small doses of salicylate of soda were no use; from 200 to 300 grains a day were required. Dr. Lees does not appear to have availed himself of salicin, which so many regard as equal to any of the salicylates as an antirheumatic and as a distinct tonic rather than depressant to the heart. It can be taken in very large doses and continued over long periods. It has been said not to cause noises in the ears, but this is an error. It does this, if not so much as sodium of salicylate.

At the Medico-Chirurgical, Mr. Hutchinson, Jr., showed a series of drawings and radiographs to illustrate dislocations of the thumb and great toe. He also related a case of acute obstruction by a band of the vermiform appendix and omentum, with general septic peritonitis, the patient recovering after operation. Mr. Hutchinson also contributed the paper of the evening, in which he described a case of volvulus of the entire small intestine, the cecum, and the ascending colon, in which operation was successful. Nine other cases had been recorded of complete volvulus. In nine out of the ten the whole intestine supplied by the superior mesenteric artery, from the duodenum to the transverse colon, had undergone torsion, bringing the cecum and ascending colon behind the mesentery, which acted as a band. In the other case the rotation was in the opposite direction. The greatly distended cecum might occupy the left iliac fossa, or might be found close to the spleen. Even after opening the abdomen the condition was not easy to recognize, and it was necessary to draw the intestines outside in order to reduce the volvulus. It was also desirable to evacuate the cecum by tapping. Only two successful operations seemed to have been recorded—Hutchinson's in 1901, and one by Brentano in 1904.

Mr. Barker said he had recorded a somewhat similar case in which the volvulus comprised the whole of the small intestine, though not the cecum, nor the ascending colon. The patient was a woman at the fourth month of pregnancy, who had undergone a gastrojejunostomy two years previously. The volvulus was untwisted without removing anything from the abdomen, and recovery occurred in ten days. The pregnancy went on to normal labor at term.

Dr. Keith expressed the opinion that the peculiar manner in which the intestine was fixed in the abdominal cavity was connected with the erect posture. He considered the case belonged to the class of congenital malformations. Mr. Hughes described a case parallel to that of Mr. Barker, in which the whole of the small intestine was involved. In reply, Mr. Hutchinson, Jr., thought his case was of a type of volvulus scarcely recognized. He disagreed with Mr. Barker as to not removing the intestines, and felt sure the omission was the cause of some failures, the condition not having been relieved because it had not been recognized.

The two great "declarations" of the profession on the use of alcohol, which were so numerously signed as to be regarded as completely representative of medical opinion in the last generation, seem now like ancient history. We have therefore been somewhat surprised by a feeble imitation of those documents in the shape of a letter to a medical contemporary signed by a few distinguished medical men, and which tends to support the moderate use of alcoholic beverages. The newspapers have got hold of the new manifesto and are treating it as far more authoritative than it deserves, for although it must be admitted that the signatures are those of able men, it is impossible to regard them as of equal weight to the old "declarations." A curious thing about the matter is that these gentlemen should just now consider the expression of their opinions called for. If intended to controvert the former declarations, it is strange they should have taken a generation to arrive at their conclusions. How came they to agree that the time had arrived when they were required to issue a joint statement of their views? It is impossible to suppose they desired to arrest the progress of the temperance

movement, or that they regarded the diminution of excessive drinking as other than satisfactory. Someone suggests to me they had been dining together, and discussed the use of alcohol afterwards, when the wine in the glass seemed moving itself aright. Others wonder whether some astute person connected with "the trade" had got hold of them. Such suggestions seem unworthy of their position, and the manifesto must be accepted for what it is worth.

At the annual meeting of the Society for the Study of Inebriety held on Tuesday the subject was naturally discussed. Dr. Harry Campbell, who presided, said the reference in the recent manifesto to the universal belief in the use of alcohol could not be the object of its issue. It was a misstatement, for such belief was not entertained by the millions of Japanese, Buddhists, Mahomedans, etc., and what he said was meant by a "moderate use of alcohol." Did it mean one glass of wiskey a day, or three, or four, or five? He had asked a person who told him that half a bottle was moderate, and if he only took two glasses he was "practically a teetotaler"—a statement which elicited laughter. Proceeding, he asked what the signatures meant by "an adult." If they meant anyone who had reached his twenty-first year he calculated that such a young person as a moderate drinker of two glasses a day consumed about eighty bottles a year, so that in fifty years four thousand bottles passed through that unromantic organ of his, the liver. Then they ought not to lose sight of the fact that the main supply of whiskey to the working classes was immature, and therefore bad. Further, if everyone restricted himself to a moderate amount of sound alcohol he could not regard the manifesto as other than misleading, harmful, and dangerous.

The King has granted another honor to Sir Frederic Treves and Sir Francis Laking in recognition of their "great skill and unremitting attention" in his illness in 1902. The new distinction is an "honorable augmentation" to their arms consisting of an addition to their shields of one of the lions from the Royal arms, which is to be borne by their descendants. The late Sir William Gull received a similar distinction—an augmentation by the Prince of Wales' feathers. It is a new form of recognition in modern times, for we must go back to Charles II. for anything similar.

Sir R. Douglas Powell was reelected to the presidency of the Royal College of Physicians on the 25th ult. In his address he gave obituary notices of nine Fellows of the College who had died during the year, and the deaths of whom I had reported on the several occasions.

The report of the Hospital Saturday Fund, of which I sent you the chief items a fortnight ago, was duly adopted at the meeting on the 6th inst.

The newspapers are according unusual space to obituary notices of Thomas Beecham. No wonder, for it is recorded that he spent £100,000 a year in advertising his pills, and what will some papers do for such a prince of puffery? The puffs gave him a turnover of £150,000. Great is the gullibility of the public!

Ed. Thos. Harrison, F.R.C.S., J.P., who died on April 3 in his eighty-eighth year, was formerly consulting surgeon to the Welshpool Dispensary. He took the M.R.C.S. and L.S.A. in 1842-3, served in the S. Wales Bonderers, and retired as surgeon-major.

OUR PARIS LETTER.

(From Our Special Correspondent.)

TYPHOID EPIDEMIC DUE TO OYSTERS—BIER'S BANDAGE FOR INFECTIONS OF THE EXTREMITIES—ELECTRIC SLEEP—THE ABOLITION OF ABSINTHE—DEATH CAUSED BY MERCURIAL INJECTIONS—NECROLOGY.

PARIS, March 2, 1907.

At the Académie de Médecine the interesting question of the part played by oysters in causing epidemics of typhoid fever came up for discussion. Netter reported the histories of thirty-three cases of the disease attributed to the ingestion of oysters coming from the city of Cette. In these thirty-three cases the symptoms appeared from ten to twenty-five days after eating the oysters, and seven of the patients died. In almost every instance the oysters had been eaten on the day of shipment and their flavor was unimpaired. The source of the trouble was therefore to be found in the oyster beds at Cette, which are situated close to the sewer outlets of the city. The Académie has appointed a commission to study the question and to make recommendations regarding the means to be taken to prevent a repetition of such occurrences.

The important subject of malaria in the French possession of Madagascar was made the subject of a communication by Kermorgant. The speaker reported on a recent epidemic of large proportions. While the disease increased rather slowly it had spread steadily, so that finally more than 274,000 cases and 13,700 deaths were reported; that is, about 5 per 100 of the population were affected. Kermorgant considered the importance of the various etiological factors, such as the mosquito, the telluric factors, and finally the squalor of the natives, and expressed the opinion that all three of these entered into the question. The enforcement of hygienic regulations and the distribution of quinine have already been followed by great improvement.

In the meeting of the Société de Chirurgie Tuffier presented a paper on the use of the elastic bandage of Bier in acute infections of the extremities. He reported the results which he had obtained by Bier's method in acute inflammatory processes of this nature excepting infections of the bone, and pointed out the necessity for skilful technique, without which success could not be obtained. The bandage itself should be a very thin strip of English rubber, not too inelastic and yet sufficiently resistant to make it possible to secure a compression which should be neither too strong nor too weak. The degree of tension could be determined at first with the finger and afterward by the patient's sensations, for pain should never be caused. The bandage should never be applied over the injury itself, but this should be covered with a dressing of dry gauze simply to protect it from the air. It should be applied at first for from twenty to twenty-two hours out of the twenty-four, diminishing gradually to about twelve hours a day. The number of applications would depend upon the duration of the inflammation. Tuffier had obtained in a general way excellent results by this method, and in cases of panaritium and of suppurative arthritis of the wrist he had secured complete and rapid cures. The method was, however, not without certain drawbacks, if there was a tendency to perspiration, ervthemas of varying degree might be produced, but this could be avoided by interposing a thin layer of bandage between the rubber and the skin. He had never seen any serious complications, such as gangrene of the limb, but to avoid any possibility of this he had always refused to make use of the method for ambulatory treatment.

Professor Leduc of Nantes has published the remarkable results he has obtained by means of his electric sleep. He gives this name to a condition comparable to chloroform narcosis, in which the subject lies without any powers of sensation or of voluntary motion, only certain reflex movements and the action of the heart and of the respiratory function persisting. This condition is produced by the action on the brain of a certain form of electric current, and may be maintained for hours, and brought to an end instantly with the interruption of the current. The current used to produce the electric sleep is intermittent, of low tension and constant in direction, that is to say, it flows for a certain period, stops, and then flows again at perfectly regular intervals. It is generated by means of a source of continuous current and of a specially constructed form of interruptor. On applying it to the head sensations of taste and of light are produced, and vertigo depending to some extent on the manner in which the electrodes are applied is caused. In order to inhibit motility and sensation the current should attain a voltage of about six, but if it is increased to ten volts respiration and heart action cease and death follows. Leduc has subjected himself to this action and has reported in a very interesting manner the sensations experienced during a period of narcosis lasting twenty minutes. A remarkable fact is, that when the flow of current is interrupted the subject awakes immediately without any of the after effects that follow chloroform narcosis.

One of the questions considered by the Society of Public Health was the abolition of the manufacture and sale of absinthe. When one reflects on the frightful ravages of alcoholism in general and of absinthism in particular, ravages that are steadily increasing and which may lead a country to its ruin, it may well be said that absinthe is a serious social peril. Legrain, physician to the Ville-Evrard insane asylum, has stated that of the 500 or 600 alcoholics who enter his service every year, the absinthe habitués form 90 per cent. It is therefore important to combat the evil and check this scourge which is threatening the future of the race.

Oettinger and Fiessinger presented before the Société Medical des Hôpitaux a case of death from mercury poisoning following injections of gray oil. The patient was a woman of nineteen years, suffering from a syphilitic ulceration of the elbow. She was given two intramuscular injections of 1 c.c. of 40 per cent. gray oil, and a third injection was given fifteen days after the second. The symptoms of poisoning did not appear until a month later, and death occurred seventy-nine days after the last injection. The mercury was absorbed very slowly, but never-

theless it was not possible to discover in the gluteal region where the injections had been made, the least nodule which might have been excised in order to prevent further dissemination of the poison. The lesions produced were especially marked in the kidneys, and consisted in changes in the cells of the convoluted tubules, the glomeruli remaining almost intact. The cells of the tubules were very largely degenerated, and this lesion explains the anuria that is nearly always observed in nephritis of mercurial origin. The speakers pointed out that most of the fatal cases of this nature have occurred when gray oil was used rather than any other insoluble preparation, like calomel for example. The case reported shows what care is necessary when injections of gray oil are resorted to in the treatment of syphilis.

French science has suffered the loss of one of its most illustrious representatives in the death of Dr. Mathias Duval, professor of histology in the University of Paris, professor in the school of anthropology, and member of the Académie de Médecine. A native of Strassburg, he was, in 1873, made assistant professor of the Paris medical faculty, and a little later he was made director of the laboratory of anthropology and professor of anatomy in l'Ecole des Beaux-Arts. For more than twenty years he had been professor of histology. He was the author of numerous books on histology and physiology which have become classics. His courses on histology always attracted large audiences that he charmed by the simplicity of his delivery and the clearness of his instruction. Among his writings mention should be made of his masterly study of the brain of Gambetta.

Reference must also be made to the death of Moissan, who was one of the most famous chemists of our period. He died suddenly of acute appendicitis in the midst of a brilliant scientific career prematurely arrested. By means of the electric furnace of his invention he made remarkable observations on the diamond and succeeded in producing artificially microscopical specimens of this form of carbon. He opened new provinces to chemistry and, in recognition of his discoveries, was awarded the Nobel prize, which he recently received in person in Norway.

OUR LETTER FROM COPENHAGEN.

(From Our Special Correspondent.)

ROVSING'S OPERATION FOR CARCINOMA OF THE BLADDER—HYPOPHARYNGOSCOPY—BRONCHOSCOPY—THE FINSEN MONUMENT—ONE HUNDRED AND FIFTIETH ANNIVERSARY OF THE ROYAL FREDERICK'S HOSPITAL.

COPENHAGEN, April 2, 1907.

At a meeting of the Medical Society in Copenhagen Prof. Th. Rovsing read a paper on a new method he had devised for the radical removal of the urinary bladder in malignant disease of this organ. When the older methods were adhered to, the ureters were left in the wound produced by the operation or were implanted into the rectum, both of which procedures were connected with grave disadvantages to the patient. With the former method urinary infiltration might take place and with both of them cicatricial stricture of the peripheric ureteral opening was not unfrequently observed, as also ascending infection of the kidneys from the cavity into which the ureters now opened. The chief original feature of the operation as performed by Prof. Rovsing is the way in which he protects the patients against the mentioned dangers. After the complete removal of the bladder he dissects the ureters entirely free for a long distance. Then he makes a buttonhole-like opening in each lumbar region, stretching from the peritoneal cavity to the skin of the back, pulls the corresponding ureter through the buttonhole, and sutures the mucous membrane of the ureter to the adjacent skin. A specially adapted silver capsule is subsequently applied to the skin of the lumbar region round the ureteral opening, and the urine is led from the two capsules to a portable urinal of the ordinary sort. This appliance has proved sufficient so that there has been no oozing out of the urine and no urinary smell attached to the patient. Prof. Tscherning and Dr. Niels P. Ernst congratulated Prof. Rovsing on the important new method. The latter speaker asked if it would not be well to secure further the efficiency of the silver capsule, by making a flap of the skin in the lumbar region and then folding this flap up in such a way as to form a penis-like prominence, on the top of which the ureter then might open.

At the same meeting Dr. P. Tetens Hald read a paper on hypopharyngoscopy, a new method for examination of the deepest laryngeal part of the pharynx, the part behind the lamina of the cricoid cartilage. The method, devised by v. Eicken of Freiburg, Germany, was demonstrated by the speaker before the members of the society. It consists in introducing a very strong laryngeal probe through the glottis into the infraglottic space, and then by means of the probe to pull the larynx forward, away from the posterior wall of the pharynx. The region behind the plate of the cricoid then opens widely and may be inspected at ease with the laryngoscope. In an obscure case, where all hitherto known methods of examination had failed to give certainty, hypopharyngoscopy had enabled Dr. Tetens Hald to diagnosticate a carcinoma of the deepest laryngeal part of the pharynx and the beginning of the gullet, and to verify the diagnosis by excision of a piece of tissue for microscopical examination.

At a meeting of the Danish Otolaryngological Association Prof. E. Schmiegelow communicated a case in which he had removed a grain of maize from the right bronchus of a child four years old by means of Killian's direct superior bronchoscopy. What gave a particular interest to the case was, however, the circumstance that the child died some hours after the removal of the foreign body, under pronounced symptoms of cocaine intoxication. Besides chloroform a quantity between five and six cubic centimeters of a 10 per cent. solution of cocaine had been used on a swab of absorbent cotton in order to procure the necessary anesthesia of the upper respiratory tractus during the somewhat lengthy operation.

About one year ago I wrote you about the war waged by the Danish sculptors against the committee for the erection of a monument for Niels Finsen, the committee seemingly not being inclined to pay the sum of money expected by the sculptors. In this farce another and very exhilarating scene has recently been played. After much debating the sum for the monument was fixed at about $10,000, and several Danish sculptors sent in their sketches. Of these sketches one has now been chosen by the committee. However, the chairman of the committee, the Danish premier, formerly a teacher in a little village school, who has proved to possess rather peculiar ideas about art and science, has had the following rider added to the acceptance of the sketch: that the sculptor remove from the monument the gloomy and heartwringing impression produced by it. Everybody is anxious to see how the happy sculptor is going to meet this trifling demand.

A few days ago, in fact, on March 31, the Royal Frederick's Hospital celebrated its one hundred and fiftieth anniversary. For so long a space of time it has been the teaching hospital of the University of Copenhagen, but now its days are counted. It goes without saying that, though it was for its time an excellent institution, and has constantly been patched up here and there, it is no longer fit to be judged according to the modern standpoint. As in a few years a new and greater hospital with the best modern equipment will be ready for the service of the University, the speeches made at the festival were most of a valedictory nature. The anniversary has also been celebrated in a scientific way, Prof. Kund Faber, with some of his present and former assistants, having published a splendid volume with papers on various questions appertaining to the pathology of the digestive organs.

Progress of Medical Science.

New York Medical Journal, April 20, 1907.

Tuberculous Peritonitis.—Several case reports are given by E. Novak, who discusses their interesting features and whose general conclusions are embodied in the following propositions: (1) the exciting cause of tuberculous peritonitis is the *Bacillus tuberculosis*. (2) This disease occurs most frequently between the ages of twenty and forty, and, according to clinical experience at least, is more common in females than in males. (3) The disease is, in the great majority of cases, secondary to a tuberculous focus in some other part of the body, most frequently the lungs. (4) There seems to be no doubt that infection through the Fallopian tubes may occur, but its frequency is disputed. (5) The onset of the disease is usually slow and insidious and its clinical course presents few definite or characteristic symptoms. (6) The diagnosis is generally difficult, and is often not made until operation or autopsy. (7) The prognosis in the ascitic form of the disease is comparatively good, and in the nonexudative variety bad. In any form it is of course correspondingly modified by the existence of tuberculous disease in other parts of the body. (8) The treatment in most cases should be operative, consisting in laparotomy, with removal of the Fallopian tubes when practicable. (9) No satisfactory explanation has as yet been offered as to the reason for the cure which so often follows operative treatment in this disease.

Cases of Appendicitis, with Comments.—J. A. Wyeth contributes a synopsis of the histories of seven cases of appendicitis and comments thereon. Concerning the technical features of the operation in general, he notes the fact that so rapid is the formation of an exudate after irritation of the peritoneum that within a few hours silk material is covered in and entirely hid beneath a rapid cell proliferation. Regarding the preferable incision, he favors the longitudinal or Deaver incision because it not only gives a perfect command of the operative field, but in cases which turn out to be complicated and necessitate a freer incision, it can be extended upward or downward indefinitely, exposing practically the entire peritoneal cavity with a minimum of danger of ventral hernia as a result of the operation. Wyeth employs the McBurney incision only where an abscess is to be opened, and under such circumstances the opening into the pus cavity is not more than a half or three-quarters of an inch in extent. This incision cannot be sufficiently enlarged to meet every emergency, without great danger of ventral hernia. The Kammerer incision, which opens the sheath of the rectus as just described, and then displaces the right edge of the rectus muscle toward the median line, holding it out of the way until the peritoneum is opened and the operation completed, is objectionable in that the replaced muscle prevents the employment of free drainage when this is found to be necessary. The method given of dealing with the stump of the appendix is, in the author's opinion, in every way preferable; it is simple and safe. So far as his knowledge goes, no accident was ever recorded against it. It can be done with the minimum of traumatism. Moreover, a number of accidents have occurred from other methods. Under no circumstances should the appendix be tied off with catgut. The method referred to consists in clamping the appendix about half an inch from its cecal attachment while slight traction is made and a No. 2 silk ligature encircles it about one-quarter of an inch from the cecum. When this is done a gauze swab is split and carried on either side of the appendix. This swab is held between the thumb and finger of the operator, grasping with it that part of the cecum immediately at the base of the appendix, which is now divided with the curved scissors about an eighth of an inch beyond the ligature. The swab prevents any possible contact of infectious material with the peritoneal covering of the cecum. The funnel shaped end of the stump is now burned by a drop of pure carbolic acid carried upon a small wisp of cotton upon a metal probe. The excess of carbolic acid is immediately removed by a drop or two of alcohol applied in the same way. The ligature is divided close to the knot, and the cecum allowed to dron back into its normal position.

Treatment of Typhoid Spine.—V. P. Gibney reviews some of the recent literature on this subject and adds the histories of two personal cases. He says that the value of the cautery as a counter irritant has proven so valuable in his hands that he prefers it to all other remedies of its class. The plaster-of-Paris jacket or corset has not proved so valuable an agent as has the simple Knight spinal base or the posterior spinal assistart of Taylor. The criss-cross strapping with zinc oxide adhesive plaster has been a valuable adjunct, especially in the milder forms of this disease. Potassium iodide has been given in certain cases, but not with any definite results. Where deformity exists, as it undoubtedly does in certain instances, it is necessary to wear apparatus for longer periods. In conclusion the author insists on the Paquelin cautery as a regular line of treatment as long as tenderness and pain on movement continues. Even after all tenderness subsides it is a good plan to employ the cautery occasionally, say once a week or once in a fortnight. It has been shown that even these deformities and areas of infiltration, bony, or muscular, disappear after a while, and fortified by this assurance, the surgeon can decide when to begin the convalescing part of the treatment, namely, douches, hot baths, and systematic graded exercises, the object of which is to correct the stiffness developed in the muscles which have been for a time out of commission, and to restore the tone generally to the spinal column.

Modified Buttermilk in Infant Feeding.—C. F. Judson and R. O. Clock give their experience in a series of twelve cases. This food should not be relied on, even with the addition of cream, for a longer period than three months, but it is a useful food in tiding over a crisis. The average composition of whole buttermilk is proteid 2.5 to 2.7 per cent., sugar 3 to 3.5 per per cent., and fat 0.5 to 1 per cent. In preparing for use the casein was considerably diluted so as to make the proportion present 1.5 to 2 per cent., and sugar added only in sufficient amounts to bring the proportion present in the mixture up to 5 per cent. Moreover, the mixture was heated only to from 140 to 155° F. for ten minutes, so that the lactic acid bacteria were not destroyed. Robinson's barley flour was added, one half ounce to each pint and a half, and cane sugar solution (6 to 9 per cent. strength) used to dilute the casein. The method of preparation of the weaker mixture was as follows: Ingredients used were one pint of buttermilk, eight ounces of a six or nine per cent. solution of cane sugar, one half ounce of Robinson's patent barley. (1) Make a paste of the flour and a small quantity of the sugar solution. (2) Add buttermilk and the remainder of the sugar solution to this paste and mix thoroughly. (3) Heat the mixture to 155° F. for ten to fifteen minutes, *stirring constantly*. (4) Remove from stove, cool, and place on ice. At first this diet gave brown, pasty, and offensive stools, which later turned to yellow. They contained mucus as a rule, showing intestinal catarrh. Later the mucus disappeared. The twelve children treated were several cases of malnutrition, marasmus, enteritis, or enterocolitis. The prostration and other toxic symptoms quickly disappeared in most cases after buttermilk diet was instituted. Eight infants gained in weight (in one the gain was only temporary), while four infants could not tolerate the diet. The gain in weight was in most cases irregular, but steadily upward, and averaged one-half ounce daily. Some gained more rapidly for shorter periods.

Journal of the American Medical Association, April 27, 1907.

The Digestion of Cow's Milk Proteids by Infants.—According to F. X. Walls the proteids of cow's milk give rise to no digestive or nutritive disturbances in young infants, and the theories now prevalent as regards the artificial feeding of infants will have to be modified. The notion of proteid indigestibility has been based on some crude test-tube experiments and the misappreciation of certain appearances in the baby's stools. The common whitish or yellowish lumps in infant stools—the so-called curds—are not proteid material, he asserts, but fats or fatty soaps; rarely are they inspissated mucus or clumps of bacteria. In hundreds of cases in which he has given fat-free undiluted milk to infants he has never after careful examination found curds in the stools. He reports two cases of infants suffering from enterocolitis fed on centrifugalized fat-free milk without any digestive disturbance and with excellent therapeutic effect. He says that there is no symptom or group of symptoms from which we can conclude that there is any injury to the infants from the albuminoid material in cow's milk, and this being shown, all the methods advocated to assist in the digestion of the proteid are without foundation and may be harmful. This does not mean that we are to feed babies on a fat-free or skim-milk diet. The normal child demands a proportion of fat in its food and this is a matter for individual determination. An excessive amount of fat, as shown by Brenneman, is the most frequent source of overfeeding, and the most dangerous foods are the cream mixtures. For a normal infant Walls would advise a dilution of one part whole milk and two parts water, gradually decreasing the dilution till in six months or a year whole milk is reached, and such whole milk containing not to exceed two or three per cent. of fat. Feeding, after the first week, should not be oftener than once in four hours in the daytime and twice at night, and the amount should be enough to satisfy the infant's appetite. The caloric value of the food taken during the twenty-four hours should be estimated as a check against overfeeding, though as a rule babies fed not over once in four hours are not likely to overfeed. The author's conclusions are given substantially as follows: 1. There is no evidence that the proteid of cow's milk causes any digestive disturbance in the infant. 2. All experiments prove that cow's proteid is easily digested and resists putrefaction. 3. The method of proteid modification as aids to digestion are therefore erroneous. 4. In sterile, fat-free milk we have an unequaled therapeutic agent in the treatment of the nutritive disorders of infancy.

Clinical and Radiodiagnostic Findings.—C. M. Cooper gives the results of four years' experience of combined use of the *x*-ray with the clinical symptoms in diagnosis, with details of a number of cases. Among these is one in which the *x*-ray revealed a bilateral functional spasm of the diaphragm, causing temporary embarrassment of respiration; others show the value of the ray in determining the presence of old apical indurations and central pneumonic patches in which the clinical symptoms alone might be misleading. He emphasizes the importance of estimating the percussion resistance, which his observations indicate to be of greater value

in diagnosis in these cases than the percussion note. The radiograms were also found of value in the diagnosis of peribronchial glandular enlargements. He believes from this evidence that intralobular effusion sometimes may be serous instead of purulent. Other conclusions reached are stated substantially as follows: So-called functional dilatations of blood-vessels are really temporary aneurysms and may change at or after death. As Tallant has shown, many persons present the Broadbent retraction of the left lower posterior chest wall. In cases in which there are no adhesions he has found that the position of the maximum retraction varies with the respiratory phases, being higher during expiration, lower during inspiration, while with adhesions this change does not happen. In patients presenting a pouch of the esophagus a change of pulse rhythm may occur, according as the pouch is empty or full, this variation being better marked during full respiration. Pericardial effusions are often unrecognized, and probably some cases of dilated hearts which have undergone extreme reduction in size from the Nauheim treatment have been instances of pericardial effusion. Cooper thinks that the correlation of clinical and Roentgen diagnosis will increase the percentage of successful diagnosis, will give certainty in various conditions which otherwise could be only suspected, will render unnecessary certain dangerous diagnostic methods, will render the clinician more skilful, will be of aid in teaching, and may be of some assistance in the relations between the physician and the patient.

Multiple Neuritis (Non-Diphtheritic) in Children.—After noticing the general opinion given in text-books as to the comparative rarity of multiple neuritis in children, H. M. Thomas and H. S. Greenbaum remark on its possible occasional confusion with anterior poliomyelitis and say that it is probably more frequent than is generally thought. Their experience in the Neurological Dispensary of the Johns Hopkins Hospital is somewhat unusual; in the past sixteen years, with an average of 1,200 new neurologic cases annually, they have seen but twenty-one cases of non-diphtheritic multiple neuritis and eight of these were in children under twelve years of age. This does not include hospital cases; the severer cases in adults are apt to be sent directly to a hospital. The children ranged between three and twelve years: three of the cases followed typhoid, in the others the etiology could not be ascertained. The clinical picture was typical in all; onset acute with lassitude, fever and loss of appetite, arms and legs both affected in every case and practically symmetrically. Electric changes generally present and deep reflexes lost in every case but one (No. 4, a possible case of lead poisoning). All the patients improved, the arms first in all but No. 4, in whom there still remains, nine years later, a paralysis of the intrinsic muscles of the hands. The recovery in all was slow, lasting over several months. Short histories of the cases are given and the symptomatology, diagnosis, etc., are discussed. The chief difficulty is in differentiating multiple neuritis in children from poliomyelitis, but the former is usually more insidious in its onset, may have an obvious cause, subjective and objective pains are more likely to be present. The widespread symmetrical paralysis is characteristic as compared with the contrary condition in poliomyelitis and the recovery is apt to be complete or nearly so. The prognosis in multiple neuritis of children is generally good. Treatment calls for removal of the cause if possible, nourishing diet, laxatives, rest in bed in the early stages, quinine in malarial cases, massage, electricity, passive exercise, mild gymnastics, and hydrotherapy are useful. Tonics may be required. If a permanent wrist or foot-drop continues, the orthopedic surgeon may be consulted.

Inoperable Cancer of the Uterus.—G. Gellhorn recommends the use of acetone as a valuable palliative remedy in inoperable uterine cancer, as it destroys the distressing odor, checks the hemorrhage, and improves the general condition. Its use was suggested by the employment of this drug in laboratory work for hardening tissues. If the ulcerated surface could be hardened during life Gellhorn assumed that the discharge could be checked until the escharotic surface could be thrown off and the process might be repeated for deeper and deeper portions. The treatment should begin with thorough shelling out of the ulcerating area. The curetted cavity is thoroughly dried with cotton sponges, the pelvis raised, and from half to one ounce of acetone is poured into the wound through a tubular speculum. The narcosis is then interrupted and the patient left in the same position for from fifteen to thirty minutes. Then, by lowering the pelvis, the acetone is permitted to run out through the speculum, and the cavity is packed with a narrow gauze strip soaked in acetone. The healthy mucosa of the vagina and vulva are cleansed with sterile water and dried. Beginning on the fourth or fifth day after the operation, the process of applying the acetone is repeated two or three times a week, without narcosis, and as the cavity decreases in size a smaller and smaller speculum can be used. The treatment almost immediately checks the discharge, which, with its odor, gradually disappears. The hemorrhages fail to recur and, with the cessation of the drain on the system, the general condition improves. The treatment causes no special pain, but anodynes may still be necessary for that due to the deeper extensions of the cancer. Urinary examinations so far have given no evidence of absorption of acetone. Two cases are reported, showing the value of the treatment when other treatment had failed.

Acute Overstraining of the Heart.—Theodor Schott discusses excessive heart straining at some length. He states that we must distinguish between acute and chronic overstrain and calls attention to the fact that the latter can result only from an accumulation of repeated single overstrains. In studying this subject Schott had wrestling performed by strong, healthy men in such manner that they alternately inhibited their movements by forcibly resisting each other, or by each lifting his antagonist. Before the wrestling began, the heart limits and the apex beat were correctly outlined, sphygmographic curves and blood pressure were registered, the position of the diaphragm and of the posterior pulmonary limits were located, the frequency of the respiration and of the pulse, the quality of the pulse waves and of the heart sounds were also accurately determined. So long as no dyspnea appeared, only an increase in the frequency of respiration was noticeable: everything else remained as before. But even in a few minutes after dyspnea manifested itself, the picture was changed. He notes in detail the changes occurring after the violent exercise, and reports cases. The article is illustrated by numerous pulse tracings and diagrams of the heart limits. He states that in acute overstraining of the heart rest is of the utmost importance, and that among drugs digitalis is in the lead. For quieting the action of the heart the application of ice or sinapisms on the anterior pectoral surface is indicated. It will hardly be possible, he states, to dispense with the use of morphine in order to alleviate the severe pains in the cardiac region, nevertheless it is advisable to be cautious in the long continued use of large doses of this drug. The use of stimulants is indicated in excessive cardiac weakness, and in threatened heart failure. When by such therapeutic means the patient is rescued from the threatening condition and when recovery from the injuries already present has taken place it may be advisable to resort to tonics to counteract the heart weakness, this being liable to persist for a considerable time. Generous nourishing of the patient is one of the most important tasks of the physician. A rational balneologic treatment, the careful use of gymnastics, suitable exercise in the fresh air, with the avoidance of any kind of straining, all come into consideration.

The Lancet, April 13, 1907.

Treatment of Prostatic Congestion by Electrical Methods.—J. S. Bolton refers to the effect of the *x*-ray on the testicles and asks if by this effect the ray will in anywise ameliorate the condition of a patient suffering from enlarged prostate. Can we hope for an effect equal to that of castration without any mutilation of the body or danger to the individual? The author notes that the patient presenting himself with prostatic trouble is usually found to be suffering from piles and congestion of all the parts about the anus. The large submucous veins of the prostatic urethra are engorged with blood and the prostate is like a sponge distended with fluid. The weakened bladder is unable to force the urine through the blocked urethra. The indications for treatment are the relief of local stasis and restoration of the circulation and the improvement in tone of the muscular fibers of the bladder. These indications are met by electrical applications. As electricity will relieve, and in many cases cure, chronic piles, so will it relieve prostatic congestion. The author adds the histories of two personal cases in both of which high frequency currents were employed with gratifying results.

One Hundred and Thirty Consecutive Extractions of Cataract without a Failure.—C. Higgins thus de-

scribes the operation. The eye having been thoroughly cleansed and cocainized he first passes a silk suture through the conjunctiva below the lower corneal margin; next direct the patient to look downwards, and having got the eye into the required position draw the suture moderately tight and have it fixed on the cheek by the thumb or finger of an assistant. He uses no other fixation. He next draws the upper eyelid upwards sufficiently to expose the upper margin of the cornea. He never uses a speculum or fixing forceps, but keeps the lid in the required position with the index finger and steadies the globe by pressing very lightly upon its inner surface with the second finger of the same hand. Then with a Gräfe's knife he makes a section in the sclerocorneal junction forming a flap of rather more than one-third of the cornea. As soon as the incision is finished he tells his assistant to let the suture go, holds it himself, and lacerates the capsule. He then removes the lens by pressure with the thumb or forefinger applied to the surface of the lower lid, just below the lower margin of the cornea, aided by counter pressure applied in the same manner above the incision. If the pressure is properly applied the incision begins to gape, the iris protrudes, the pupil dilates, and the lens escapes through it. Having removed the bulk of the cataract he takes care to press out all cortex, and then if the iris has not returned to its normal position he replaces it by rubbing the upper lid lightly upon it and if that does not suffice he pushes it back with the curette. In some cases pressure through the lid will not cause the lens to escape; in such he removes it by light pressure with the curette applied directly to the eyeball. He never hurries over the operation, but when the lens has been entirely removed and the iris has returned to its normal position he leaves the eye exposed to the light for a few moments; by so doing the pupil contracts and remains contracted and the risk of prolapse is lessened. After the operation he covers both eyes either with a pad of wool and gauze or Gamgee tissue, or pads specially made for the purpose, secures the pads by a light bandage, and puts the patient to bed, where he remains for three days. He removes the dressing on the second day, but reapplies it, and afterwards dresses the eye every day, but keeps both eyes bandaged for a week, without opening either unless there is some special reason for doing so, such as pain, swelling, or redness of the lids, or unusual discomfort. If prolapse of the iris occurs to any considerable extent he removes it as soon as found; small prolapses he leaves alone.

Pathology of Melanotic Growths.—W. S. Handley, in a further lecture on this subject, discusses among other topics that of the clinical diagnosis of malignancy and moles. He says that when a pigmented wart or mole increases in size, ulcerates, or gives rise to bleeding and discharge, it should invariably be treated as a malignant tumor. To wait for the establishment of the diagnosis by palpable enlargement of the regional lymphatic glands is to court trouble. The complete operation as for removal of a melanotic sarcoma should be carried out. The removal of the surgical lymphatic glands is not a very severe surgical procedure as an insurance policy against such a terrible surgical disease. Some surgeons may consider, wrongly in the author's opinion, that removal of the glands is unjustifiable until conclusive evidence of the malignancy of the tumor has been obtained. For this purpose microscopic examination of a small portion of the primary tumor is often valueless, for an innocent mole may present the typical appearance of an alveolar sarcoma. Proof of malignancy can only be obtained by a systematic examination of the whole of the excised piece of tissue at the center of which lies the suspected mole. Two adjoining diametric slices are taken, vertically to the skin surface, through the center of the suspected tumor. Each slice should be about one-eighth of an inch thick. The slices are fixed, hardened, and cleared. One of them is preserved as a translucent naked-eye specimen; the other, divided into pieces of suitable size, is submitted to microscopic examination. If beyond the limits of the primary growth in the naked-eye specimen any trace of black cords or dots can be seen, and if in the microscopic specimens permeated lymphatics or perivascular infiltration can be detected beyond the obvious edge of the neoplasm, the malignancy of the tumor is shown beyond the possibility of doubt. Removal of the regional lymphatic glands must in such a case be undertaken without delay. If the surgeon waits for obvious enlargement of the lymphatic glands, permeation of their tributary and efferent trunks may probably by that time have carried the disease beyond the reach of his knife.

British Medical Journal, April 13, 1907

Relative Opsonic Power of the Mother's Blood Serum and Milk.—This question has been considered in a series of experiments by E. Turton and R. Appleton. From their results it would apear that while the opsonic power of the mother's blood serum for both the tubercle bacillus and the *Staphylococcus pyogenes aureus* is within the normal range, that of the milk from the same source is very low, averaging 0.077 for the tubercle bacillus and 0.11 for the *Staphylococcus pyogenes aureus*. The cow's blood serum appears to have about half the opsonic power of human blood for the tubercle bacillus and rather more for the *Staphylococcus aureus*. The presence of antitoxin has been demonstrated in the milk of animals immunized against various toxins, *e.g.* tetanus and diphtheria toxins. It has also been shown that the milk of animals immunized against the typhoid bacillus and of mothers who have suffered from typhoid fever contains agglutinins for that organism, but it would appear that the amount of these protective substances in the milk is very much less than in the blood. Comparisons of the opsonic power of the child's serum with that of the mother's serum and milk showed that the opsonic power of the child's serum was much less than that of the mother, and the authors consider it an interesting question whether any absorption of opsonins can take place from the mother's milk. They note that authorities seem to be divided on the question of absorption or nonabsorption of agglutinins and antitoxins in the intestinal canal of children.

Suggested Modification in the Opsonic Estimation of Tubercle.—R. D. Campbell has found that for opsonic estimation the tubercle bacilli may be prepared stained beforehand. In common with ordinary dead tubercle bacilli, the stained bacilli in simple admixture with leucocytes are not taken up, but, like the ordinary bacilli in the presence of serum, the dried bacilli were roughly powdered and then placed in a fair quantity of carbolfusehin and stained in the cold for twenty-four hours. The mixture was then centrifugalized, the supernatant fluid siphoned off, and the sediment shaken up with distilled water. This process was repeated three of four times to wash the bacilli. The sediment of stained bacilli was then used in the same manner as the ordinary bacilli, ground with saline solution in an agate mortar, and the bacillary emulsion prepared as usual. The stained bacilli may be kept as a stock. The process is then as usual up to the staining of the films, when, instead of the carbolfuchsin and counterstaining process, a self-fixing blood stain is used, Jenner's being, perhaps, the best. With this stain very fine films may be obtained, with only one slight disadvantage—that the fine eosin-stained granules of the polymorphonuclear leucocytes are apt to cause confusion with the fuchsin-stained bacilli. With experience, however, the difficulty is slight. The fact that bacilli treated with such a powerful stain as carbolfuchsin, containing roughly about 46 per cent. carbolic acid, can be influenced by the opsonin to the extent of allowing phagocytosis is of interest. Is the virus, asks the author, contained in the bodies of the dead bacilli neutralized by the staining process? If so, then there must be another nonvirulent body present, which, in combination with the opsonins in the serum, forms the substance causing chemotaxis in the leucocytes.

Vaccine Treatment of Tuberculosis in Children.—C. Rivière believes that in tuberculin we have a most valuable remedy for localized tuberculosis. There is nothing dramatic in its effects, but, with proper dosage, a steady uphill progress occurs both in the local conditions and in the general health. That this improvement corresponds with an increase of opsonic power the author has satisfied himself by observing the alternate improvement and relapse in superficial lesions with the rise and fall of the opsonic index of the blood. Tuberculin, especially suitable for localized tuberculosis, is also of value in many cases of less localized infection, especially if nutrition be not greatly impaired. Many of the author's cases appeared hopeless from the outset, being either chosen for the purpose of testing the limitations of tuberculin or handed over to him because other treatment had failed. With marked wasting and general illness no good results should be expected; yet even under such conditions tuberculin is occasionally the turning point in a downhill course, so that unless the lesions are known to be widespread it is still worthy of trial. Tuberculin cannot take the place of surgical procedures but should be used in conjunction with these. Especially must caseous material, unless small in quantity, be removed, and this should be done at a time when the opsonic index is at a high level. On the other hand, many cases would escape the necessity for surgical measures if tuberculin were given sufficiently early. The secondary infection, always present with open tuberculous lesions, generally lessens with improvement in the tuberculous process. The advantage of and occasional necessity for a second vaccine is a point to

which the author is giving special attention. Tuberculin treatment should only be undertaken by those who have given it special study. This must be obvious to all who remember the results of its use in the old days.

The Influence of the Antituberculous Serum on the Opsonic Index.—Histories of five cases are given by W. C. Bosanquet and R. E. French. These cases were heated with Marmorek's serum and from their experiments the authors conclude that a series of doses of this serum will, when administered rectally, usually produce a rise in the tuberculoopsonic index; this rise begins after the first three or four doses and soon reaches a maximum, close to which the index remains for three or four weeks, while serum is being given, and does not fall till nearly a week after injections have been omitted. This rise in the opsonic index is coincident in some cases with an improvement in the general condition of the patient and a diminution of the diurnal variation of the temperature. Subcutaneous injections of the serum do not seem to have such a good effect; possibly a series of such injections given at longer intervals might be preferable as avoiding an accumulation of negative phases. If, as is suggested by the authors' experience, a rise in index is produced by the administration of Marmorek's serum, but is not maintained for long after the serum has been omitted, the action of the serum might be explained by its containing an excess of opsonins. This, however, is scarcely to be expected, as a serum, when kept *in vitro*, gradually loses its opsonic power, so that at the end of two weeks the index is only about an eighth part of what it was when the serum was fresh. To prove that Marmorek's serum was not loaded with opsonins the authors tested its opsonic index in the usual way; in the slide made from normal serum they found 568 tubercle bacilli in 200 polymorphonuclear leucocytes, and in the slide made from Marmorek's serum only 72. This gives an index of 0.127. Some other explanation, therefore, must be found for the action of Marmorek's serum.

Münchener medizinische Wochenschrift, April 2, 1907.

The Treatment of Gangrene Due to Arteriosclerosis.—Ropke refers to the fact that where this variety of gangrene is present in the toes, an amputation is usually accepted as the only form of curative treatment. It is not always easy to know, however, to what point the tissues are still in such a condition that recovery may take place. The loss of pulsation in the dorsalis pedis or the posterior tibial arteries need not always prove a contraindication, as shown in the case reported by the writer. The patient was a gouty man of fifty-nine years of age, who developed a gangrene of the toes and at the same time showed an absolute loss of pulsation in the two vessels mentioned. The patient would not permit anything more than an exarticulation of the toe, which was accordingly done and the tissues found to be bloodless. The process extended and required further removal. Hot antiseptic foot baths were then employed for cleansing purposes and the writer was surprised to find that the previously exsanguinated areas began to bleed. The hot baths were repeated daily and after a period of eight days pulsations could be detected in the dorsalis pedis artery. The wound also gradually healed. The procedure indicated apparently constitutes an efficient diagnostic and curative measure in these cases.

Tuberculosis of the Eye Treated with Tuberculin.—Erdmann reports an instance in which this agent was applied in the treatment of a case of tuberculous iridocyclitis in a young girl who was also afflicted with tubercular arthritis. Koch's new tuberculin was employed, the solutions being made with normal salt solution in order to avoid the irritation usually produced by glycerin. The initial dose was 2/1,000 mg. injected into the upper arm every other day. The quantity was increased by this same amount at every treatment until 10 1,000 mg. were given. Fever and headache were then complained of and a local reaction was noticed in the eye. The dose was again increased until 4/10 mg. was given, and during a period of four months the patient had been given sixty injections. No other treatment aside from the use of a dark glass and the occasional instillation of atropin was employed. The eye became practically well again and the patient's general condition was improved at the same time. No recurrence was noted up to the time the report was made, although no further injections had been given in almost a year.

Deutsche medizinische Wochenschrift, March 21 and April 4, 1907.

Pseudoleukemia with Periodical Attacks of Fever.—Tschistowitsch describes a condition of high-grade anemia in a woman who was greatly emaciated and in whom there were attacks of fever lasting from ten to fourteen days, alternating with similar periods in which there was no rise of temperature. The writer states that there is no other infectious disease which presents the same temperature curve and from the fact that a number of similar cases have already been observed by others, he thinks that we may regard this condition as a clinical entity to which he has given the name "pseudoleucæmia cum febri periodica." During the febrile attacks the spleen and the liver become enlarged and during the afebrile interval these organs return to their normal size. Later on in the disease they remain more or less enlarged all the time. The lymphatic glands are also enlarged. In all cases which are known from the literature there is progressive loss of strength and anemia without any increase in the white blood cells. During the afebrile intervals the patients feel quite well. The disease seems to be invariably fatal, although in the author's case a recovery seems to have taken place. He attributes this improvement to the administration of potassium iodide, and for this reason believes that syphilis must be regarded as an etiological factor in the production of the condition. This also seems to be borne out by the clinical histories of the other reported cases.

The Treatment of Mediastinal Tumors with the Roentgen Rays.—Elischer publishes a further report on two cases of mediastinal tumors treated with the Röntgen rays, in which the effect of this agent could be studied in the autopsy findings. In both of these cases the *x*-rays brought about a marked improvement in the patients' condition, although they later succumbed to the effects of the metastatic deposits. The autopsy showed that the tumors were sarcomata of a very malignant type, but in the mediastinum they had been largely replaced by connective tissue. The author is of the opinion that if the application of the *x*-rays had been made earlier, before any metastatic development had taken place, a more permanent cure would have resulted. The cases are interesting as being among the first in which such a demonstration of the effects of the rays was possible.

Enteritis and Appendicitis.—Sonnenburg refers to the difficulty in making a diagnosis when the symptoms are those of a general intestinal or peritoneal infection and there are very few local signs. An example of this is the gastroenteritis which may follow an influenza, where the pains are of a colicky character, marked by a sudden onset, and accompanied by a high fever and a rapid pulse. The leucocyte count is low, however, and this, according to Sonnenburg, constitutes one of the main features in the differential diagnosis. A secondary appendicitis is not uncommon after these attacks and unfortunately its prognosis is usually bad. Where there is any doubt, however, of the presence of a mere catarrhal condition of an influenzal or similar character, the administration of a suitable dose of castor oil will clear the intestine and often alleviate the symptoms. Sonnenburg claims that this remedy will not increase the danger of perforation or gangrene in an inflamed appendix by merely increasing the peristalsis. One should always be prepared, however, to do an immediate operation if no relief is secured.

Chronic Articular Rheumatism and Arthritis Deformans.—Hoffa refers to the uncertainty which exists regarding the pathological classification of these diseases. He claims that there is a distinct difference between the two and that a classification may be made which is based on etiological factors. Three groups of chronic joint diseases may be recognized: (1) A typical arthritis deformans; (2) a chronic progressive polyarthritis or destructive polyarthritis, and (3) a chronic articular rheumatism which follows an acute variety of the same. As regards their etiology, these may be classified as infectious or non-infectious, although much of the following scheme rests largely on hypothesis. The non-infectious group includes chronic traumatic, irritant, constitutional, deforming, and functional arthritis. The infectious group includes both primary and secondary varieties. Hoffa finds that in these chronic cases various forms of braces and supporting apparatus is often of greater value than the medicinal or physical measures.

The Transmission of Syphilis to Dogs.—Fromme reports the results of his preliminary experiments with the inoculation of syphilitic virus from the human subject in dogs. In two cases bits of a penile chancre were inoculated in the anterior chamber of the eye and soon afterward a typical specific keratitis resulted. The period of incubation was sixteen days in one case and twenty-one in the other. The *Spirochæta pallida* was also obtained in smears made from material taken from these ocular lesions. Further experiments in this direction are promised at a later date.

Book Reviews.

Essentials of Medical Electricity. By Edward Reginald Morton, M.D., C.M., Trinity University, Toronto; D.P.H., Fellow of the Royal College of Surgeons, Edinburgh; Medical Officer in charge of the Electrical Department London Hospital; Honorary Secretary of the British Electrotherapeutic Society, etc. With eleven plates and seventy illustrations. Chicago: W. T. Keener & Co., 1905.

In this little volume the author has succeeded in presenting the essentials of this important subject both clearly and concisely. The book is well written, readable, sufficiently illustrated, and is a good example of the best class of compend.

Jahresbericht über die Leistungen und Fortschritte auf dem Gebiete der Erkrankungen des Urogenital-apparates. I. Jahrgang, Bericht über das Jahr, 1905. Berlin: S. Karger, 1906.

This work is similar to others issued in Germany in which is considered the progress made during a given time in some special field of medicine. It is believed to afford a complete and ready means of reference to what has taken place in the science of urology during 1905, and a glance through its pages will show that the labor expended on this subject has been enormous. It is evident that the constantly growing literature has been reviewed in order to be made accessible to the body of the profession as well as to the specialist. The book opens with an account of the life and labors of Nitze, who was one of the founders and editors of the book and is generally recognized as a leader in the field of genitourinary diseases. The manner of arranging the text is very convenient; each writer is given a paragraph containing a brief abstract of his paper and each division is supplemented by a voluminous bibliography. The work is very complete and will undoubtedly meet with a favorable reception among those engaged in this particular field of medicine.

Conservative Gynecology and Electro-Therapeutics. A Practical Treatise on the Diseases of Women and Their Treatment by Electricity. By G. Betton Massey, M.D., Attending Surgeon to the Oncologic Hospital, Philadelphia, etc. Fifth Revised Edition. Philadelphia: F. A. Davis Company, 1906.

The work under discussion is one of a comparatively small group devoted to the electrical treatment of gynecological affections. Electricity is undoubtedly a most valuable therapeutic resource, but its universal application to almost every phase of gynecological disease is a visible departure from the realms of common sense. As a means of aiding diagnosis it can in the form of appropriate apparatus be said to constitute a most efficient aid to gynecological practice, but as a cure for all pelvic conditions from fibroids to cystocele it will hardly meet with general approval. The book is an excellent example of what enthusiasm in the belief of one therapeutic resource will lead to—an enthusiasm which leads the author, who has set out to write a book on gynecology, to devote a chapter in the middle of the book to the cosmetic application of electricity. The chapter on the treatment of uterine fibroids by the electric current will probably meet the greatest amount of attention because it is in this field that the author has been most frequently heard. The final result in the 110 cases thus treated is hardly favorable and some of the measures advocated, such as abdominal puncture with a special electrode, will hardly appeal to one on the score of safety. About half the book is devoted to the technique of the various procedures advocated in the previous chapters, and impresses one with the exceeding complexity and corresponding expense of the apparatus needed for carrying out these methods of gynecological treatment

Indications for Operation in Disease of the Internal Organs. By Prof. Herman Schlesinger, M.D., Extraordinary Professor of Medicine in the University of Vienna. Authorized English Translation by Keith W. Monsarrat, M.B., F.R.C.S. Ed., Surgeon to the Northern Hospital, Liverpool. New York: E. B. Treat & Co., 1906.

The far-reaching activities of modern surgical endeavor make the appearance of a book of this kind opportune, for the question of operation is one which constantly presents itself to the general practitioner and is often very difficult of decision. To meet this want the book in question has been produced. Prof. Schlesinger is one of the best known clinicians in Europe and the book is the result of his many years of practical experience. Although written by one who is essentially an internist and physician, there is no lack of sympathy for the surgeon and his aims. All discussion has been avoided, but in each chapter are included a few remarks on the etiology, pathology, clinical course, diagnosis, and differential diagnosis, in order that the subject under consideration may be more thoroughly grasped and appreciated. The main purpose of the undertaking, however, is to enable the general practitioner who is not in hospital practice, to arrive at an independent opinion on the advisability of operation in the presence of internal lesions. The scope of the book is quite extensive, all the structures which may be included in a general way in the interior of the body being separately discussed. At the end in an appendix, are three very good chapters on the induction of premature labor, operations on diabetics, and the general influence of operations on the body. The book is well written and not burdened with illustrations for which there is no necessity. It will undoubtedly meet the demand for which it was written, as it stands practically alone in this field.

The Technique of Operations upon the Intestines and Stomach. By Alfred H. Gould, M.D., of Boston. Philadelphia and London: W. B. Saunders Company, 1906.

This book may be regarded as a departure in works on surgery, as it practically represents the results of an extended research expressly undertaken for the purpose of simplifying or improving the best known gastrointestinal operations. The experimental study of the technique was made upon animals, mainly cats and dogs, and then carried out on the human cadaver for purposes of anatomical corrections. Not all the methods in vogue are given, but those included will afford to the reader a sufficiently comprehensive view of the requirements of gastrointestinal surgery. The opening chapter includes an account of the very interesting studies on the " pair of intestinal wounds made by the author in conjunction with Dr. F. B. Harrington which are already well known. The technique of operation is considered in great detail and constitutes a very valuable feature of the book. The suggestions are too numerous to mention here, but all have been thoroughly tested by the author in his extended operative experience. The text is clear and concise, although in some instances conciseness is obtained at considerable sacrifice of other desirable qualities. A few words must be added regarding the illustrations, which are beautiful and often help out where the text fails in being sufficiently explanatory. They are well drawn and well executed and constitute an important factor in what will certainly prove a most acceptable book on surgical technique.

L'Evaluation des Incapacités Permanentes, Basée sur la Physiologie des Fonctions Ouvrières des Diverses Parties du Corps. Par le Dr. Ch. Remy, Professeur agrégé à la Faculté de Médecine de Paris, Membre de la Société de Biologie, Chirurgien Honoraire de la Maison Départementale de la Seine. Avec 63 figures dans le texte. Paris: Vigot Frères, 1906.

This book fills well a place which no book in English more than attempts to occupy; only one does this and even its author recognized its tentative development, while this one has a logical foundation which gives it a peculiar value to the special public for which it is intended, the adjusters of the companies, which by insuring the workmen of an industry against the accidents of their daily tasks protect the employer from "accident suits" for damages. Hitherto, both since the passage of the "new law" and previously, the basis of settlement has in every case been by mutual agreement on an arbitrary valuation in which the agent of the company endeavored to settle for the lowest possible figure and the injured workman or his agent attempted to get all he could, and usually neither was satisfied. The aim of Dr. Remy is to substitute for this unsatisfactory system another having rational foundation. While for the most part the discussions are technical, some have very general interest.

La Régénération des Familles et Races Tarées. Prophylaxie et Hygiène Thérapeutique de l'Hérédité Morbide. Par Dr. E. Contet. Paris: Vigot Frères, 1906.

This rather unusually interesting book treats of a subject much too seldom considered, the consideration of the physical condition of the possible parents and their family inheritance of physical and mental traits in relation to their possible and probable offspring. In effect it is an amplification and development, in large measure a fulfilment, of the precept in Raymond's book of last year, l'Hérédité Morbide,—that it is the duty of the family physicians to point out to the contracting parties the consequences of physical misdoing, as their legal adviser might advise them not to break the law of the land. The book is well written and certainly sets the reader thinking, whatever his opinion of the author's teaching may be. It is well, very well, worth reading, and we trust that an English translation will not be long delayed.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held April 5, 1907.

DR. JOHN F. ERDMANN IN THE CHAIR.

A Case Showing Result of Operation for Habitual Dislocation of the Patella by a Modification of Krogius' Method.—Dr. WILLIAM C. LUSK presented this patient, who was forty-one years old. Six years ago, while running, he slipped on some ice and fell over backwards, dislocating both his patellæ outwards. Afterwards, always on flexion of the legs, the patellæ slipped outward over the external condyles. He was admitted to Bellevue Hospital and operated on January 14, 1907. The right knee was operated upon by a modification of Krogius' method. Krogius divided the aponeurotic structures down to the capsule of the joint along the outer side of the patella and the iliotibial band above to relieve the shortened tissues on the outside of the joint, then making a musculo-aponeurotic flap on the inner side of the joint without entering the joint on this side either, he carried this flap in front of the quadriceptus extensor tendon around the upper border of the patella and laid the extremity of it in the wound which had been made in the aponeurotic structures at the outer side of the joint and sewed it there. Then the edges of the wound at the inner side of the joint, made by the removal of the musculo-aponeurotic flap, were sutured together, thus shortening to this extent the tissues at the inner side of the patella, by the support of which the tendency to outward dislocation would be counteracted. The operator in this present case found it necessary to carry the incision for the relief of the restraining structures at the outer side of the patella, upward and inward through the muscle fibers of the vastus externus to the outer edge of the quadriceps extensor tendon. Then finding furthermore that by Krogius' method only the tip of the musculo-aponeurotic flap would reach into the wound in the divided structures at the outer side of the joint, instead of carrying this flap in front of the quadriceptus extensor tendon, he made a blunt dissection beneath the tendon above the subquadricipital bursa and carried the flap through the opening thus made and then laid it in the musculo-aponeurotic wound at the outer side of the knee-joint, which it was found to fit accurately from its upper limit down to within half an inch of its lower end. The flap was sutured in place with chromic gut. An anatomical specimen was shown illustrating the *surgical anatomy* of the operation. The outer edge of the aponeurotic insertion of the vastus externus into the patella, receiving the terminations of the muscular fibers, corresponded to the edge of the underlying portion of the subquadricipital bursa, so that division of the muscular fibers above this line could be made without entering the joint. The division of the muscle fibers at this situation was an important part of the operation since they were shortened and on flexion of the leg they alone pulled the patella outward over the external condyle, after the shortened tissues attached to the outer border of the patella had been cut. It seemed equally important that this upper muscular portion of the wound made at the outer side of the knee-joint to relieve the shortened tissues, as well as the lower aponeurotic portion, should be filled in by the transplanted flap from the other side, so as to prevent a hard scar from forming at this situation where a re-establishment of pliability instead seemed essential. A branch of the superior internal articular artery entered the muscular portion of the flap transplanted from the inner side. The width of the flap was planned so as to remove the exact amount of tissue that would leave behind edges of muscle and aponeurotic structure of a sufficient length to be brought together with the right amount of tension to hold the patella firmly inward. The result of the operation was primary union. On March 12, 1907, the patient gave up the use of his cane, no longer having the feeling of insecurity in his gait. On April 5, 1907, he had voluntary flexion of the right leg of ninety degrees, and forced flexion of about another ten degrees. The right patella did not dislocate.

A Case of Fracture of the Patella.—Dr. CLARENCE A. MCWILLIAMS presented a man, who had been admitted to the hospital last May, two days after he received an injury to the left knee. He fell down an areaway, striking a board. He then walked one block and, two days later, was admitted. There were two infected skin wounds. It was impossible to palpate the bony structures at all, but the *x*-ray plate showed the patella fractured in five or six pieces. Twelve days after the injury he was operated upon, the operation having been delayed because of the infected wounds on the knee surface. He preferred the transverse rather than the vertical incision, because it allowed the lateral tears in the vasti expansion to be sutured. Three loose pieces of bone were removed. The joint was filled with blood, which was spooned out and the cavity cleansed. A purse-string suture was placed around the remaining fragments, as well as a vertical one. The joint was kept in splints for twenty-one days, then massage was given and the patient was allowed to walk on the twenty-eighth day. He made a good recovery.

DR. HOWARD LILIENTHAL believed that these were the cases that should be treated by operation, and he congratulated Dr. McWilliams upon the beautiful results obtained. In the ordinary transverse fractures, however, he had been in the habit of using a massage treatment. In this non-operative treatment the patient was out of bed, but in splints, on the eighth day, and a cure was accomplished which was as perfect as in the patient presented on the forty-eighth day. He called attention to the fact that King Edward's fractured patella was not sutured and yet good results were obtained. In cases of comminuted fracture, however, operation was proper; also, in open fractures.

DR. JOHN F. ERDMANN asked Dr. Lilienthal what he did, in this massage treatment, to bring the fragments together.

DR. LILIENTHAL said that the first thing to do was to place an arrangement of tapes above and below the patella, strapping the fragments together, an ordinary bandage being placed on. During massage, however, everything was taken off, and the fragments held in place by an assistant. The massage was given with the limb in an inclined plane, completely relaxing the quadriceps muscle. Massage should be begun above and continued down. It should be given fifteen minutes both morning and afternoon. On the eighth day it was supposed that adhesions had taken place which would hold the fragments together and the patient then was allowed to get up, but with the splint on.

DR. MCWILLIAMS said that, if the separation was half an inch, he always operated, and with magnificent results.

DR. LILIENTHAL said that Dr. McWilliams was very fortunate in not having seen or encountered infection of the knee joint following the opening of an aseptic articulation. He had seen several such cases, and one need only see it once to make him extremely careful in operation about this joint.

DR. ERDMANN said that he never opened the knee joint without fear and trepidation.

DR. A. ERNEST GALLANT said that he had had cases treated by the rest treatment and massage, relieving the adhesions which had formed, and he thought that Dr. Lilienthal had not been given sufficient credit for the good results he had obtained.

Extensive Removal of Bone after Depressed Fracture of the Skull.—Dr. JOSEPH B. BISSELL presented a man who had been admitted to Bellevue Hospital on September 14, 1905. He had been hit on the head by a falling brick, was brought into the hospital on a stretcher, and recovered consciousness in the ward and never lost

it afterwards. A cut on his head was three inches in length, and a depressed fracture was found when the wound was being dressed. The next day he developed symptoms of paralysis of the left leg and arm. The depressed fracture was cut down upon and a large amount of bone was removed. The longitudinal sinus bled profusely. The patient made an uneventful recovery so far as the head lesion was concerned. Within five or six months epileptiform convulsions appeared, but consciousness was never lost until recently. These attacks had increased lately. He had also recently gastric crises. There was partial anesthesia of the left arm. He had great difficulty in getting up from the chair and he dragged the left foot.

Dr. Howard Lilienthal asked if another operation was not indicated in order to loosen possible adhesions; he thought this to be strongly indicated, especially in view of the fact that the epilepsy had only recently developed. The patient, too, should be carefully watched during an attack. He had had a child with such attacks and he saw the patient in several of them. During the attacks the scar was drawn in. He believed that in this case there was a decided indication for the removal of more bone.

Dr. Bissell replied that at the first operation much bone had been removed. At the same time he believed that the indications now pointed to another operation.

Drainage in Operations upon the Biliary System.—Dr. Howard Lilienthal read this paper. He said that the surgery of the biliary passages was still in a decidedly unfinished state, and in spite of the earnest work of many conscientious surgeons. The number of deaths, except in the uncomplicated cases, was still great. Operative recovery after work upon an uninflamed gall-bladder was almost constant, and the percentage mortality after the simpler operation upon this viscus, even in acute cases, was low. When jaundice appeared as a complication, however, and surgical interference with the common duct was required, the picture changed, and even in the most skilful hands the death rate was shocking. The impressions recited in his paper were from a collected experience with more than 300 cases, including examples of nearly every known operative procedure on the gall-bladder and its associated ducts. He had reached the conclusion that in operative jaundice, especially the chronic variety, the skilful use of biliary drainage was the most essential measure in reducing the operative mortality. He also believed that the longer the jaundice had existed the greater must be the caution in relieving the condition. Chronic obstruction led to secondary cirrhosis of the liver with its attendant dangers, not the least of which was hemorrhage; also, just as reflex anuria might occur after the operation for the relief of renal obstruction, so in long-continued hepatic blocking, constant, or intermittent, the attempted surgical drainage of the liver through its ducts might be followed by suppression of bile. This suppression might be gradually relieved after a few days, or it might persist and become the cause of a fatal cholemia. He then gave illustrative cases. Dr. Lilienthal summed up the vital points of this subject as follows: (1) That the scientific and judicious employment of preliminary drainage in obstructive jaundice would probably lessen the dangers of such steps as might be necessary for permanent cure. (2) That this drainage should form the sole object of the surgeon's work until the factor of cholemia had become eliminated. (3) That radical operations should, in most chronic cases, be postponed until hepatic engorgement and icterus no longer existed.

Dr. Samuel Lloyd said that the point brought out by Dr. Lilienthal regarding the deaths from cholemia had bothered all of them.

Dr. Joseph B. Bissell said that the conclusions given by Dr. Lilienthal were very valuable. He had had many cases in which he wished that he had not finished the operation at one sitting.

Dr. John F. Erdmann reported a case that he had operated upon for cholangitis and had washed the liver out well. The other day he washed the hepatic ducts out, getting small stones and sand. This was followed by hemorrhages from the nose and stomach and death.

Dr. A. V. Moschcowitz said that many might consider his views somewhat erratic, but he had never been a believer in hepatic drainage. It always appeared to him that, in all cases requiring drainage, the common duct was either free, or it was not free. If it was not free no operation was complete until it was made free; but if the common duct was made free there was then sufficient drainage into the intestine.

Dr. Lilienthal, in closing the discussion, said that some had missed the point of his paper, because he agreed with what had been said. In one of the cases he recorded he took out the gallstone and sutured the parts. If there was a deep jaundice, a chronic jaundice, the correct thing to do was to drain the gall-bladder and to drain it slowly. He emphasized the importance of draining the liver through the gall-bladder by a slow method, and gradually increasing the flow and avoiding shock. If icterus was present, attack the common duct and remove the obstruction and complete the operation.

New Operation for Cystocele in Women.—Dr. J. Riddle Goffe presented this communication, illustrating his remarks with diagrams. He presented what he claimed to be a novel procedure for the cure of cystocele. After reviewing the history of the various operations for the cure of cystocele in brief, he said that these previous operations had two objections: first, in attempts to diminish the size, wrinkling up the base of the bladder, sulci were left in which urine would accumulate; second, the fundamental principle which underlay the question, trying to get support *under* an organ to hold it up. Dr. Goffe said that nature's plan of retaining organs in place was not in placing anything *under* an organ, but in *suspending* it from a bony framework. The uterus was not held up, but was supported by ligaments in accordance with nature's law. The bladder normally was suspended by its ligaments which hung from above; it was supported chiefly by its attachment to the uterus, the broad ligaments, and the lateral fascia on either side. It was the giving way of that support, as well as the giving way of the fascia at the base of the bladder, that produced the hernia they must deal with. Dr. Goffe's plan was to dissect away the bladder, freeing it entirely from all structures except those above. He then rotated this viscus on its transverse axis, carried it up, and stitched it to the uterus. The work was done per vaginam. The technique of the operation was described. He had had from fifty to sixty cases under observation and the results so far had been entirely satisfactory. He had not yet learned of a single recurrence.

Dr. Herman L. Collyer said that all knew what dead failures the operations for the cure of cystocele had been, and believed that this operation described by Dr. Goffe was the first that offered them chances of success.

Dr. Howard Lilienthal thought that the operation was a perfect anatomical one. He asked Dr. Goffe if the male bladder was suspended or not. He believed the male bladder was supported "from below."

Dr. Joseph B. Bissell said that most cystoceles were due to prolapsus uteri, and he asked if Dr. Goffe did not first fasten the uterus up. He did not see how one could suspend the bladder without first suspending the uterus.

Dr. Howard Lilienthal asked Dr. Goffe if he had had pregnancy following this operation he described, and with what results.

Dr. Smith of Hartford, Conn., said that the Mayos, in Rochester, Minn., had been doing successfully the old-fashioned English operation, which was similar to the one described by Dr. Goffe. But they did it in women past the menopause and not in young women.

Dr. J. Riddle Goffe, in answer to Dr. Lilienthal, said that anatomists did not describe differently the male and

female bladders in regard to the supports. In answer to Dr. Bissell's query, he said that the uterus must be supported before a cure of the cystocele could be effected, first shortening the sacrouterine ligaments. He had had two patients that became pregnant after this operation and they went through all right.

The Surgical Anatomy of the Esophagus.—Dr. CHAS. R. L. PUTNAM presented this communication. The esophagus began at the lower border of the cricoid cartilage, which was opposite the sixth cervical vertebra, or the intervertebral disc below it. It ended near the level of the eleventh dorsal. From its origin to the second dorsal it was called cervical; from that point to where it passed through the diaphragm it was called thoracic; from this point to where it entered the stomach it was called abdominal. Its total length was 25 c.m., the cervical portion averaging 5 c.m., the thoracic 15-17 c.m., and the abdominal 3-4 c.m. The caliber of the esophagus varied very much at different levels, as shown by casts and drawings that he presented. It was shown that the least distensible places were at the beginning and at a point behind the summit of the aortic arch. This point might be pressed upon by aneurysm of the arch, and, therefore, constriction in this region should have history and physical signs most carefully studied. These narrowings, as shown by the casts, had surgical significance as follows: First, they were supposed to determine the points at which ingested caustic solutions would be most apt to be the cause of ulceration and stricture; second, they might cause an arrest of foreign bodies; third, where the narrowing in the esophagus was partly due to relations of other organs, changes in the latter might increase the degree of narrowing to the extent of producing a clinical stricture. Thus aneurysm of the aortic arch was said to cause dysphagia; he also had been told of a case of pericarditis giving this symptom. Enlargement of the peribronchial, peritracheal, or esophageal lymph nodes might produce the same result. This accounted for the apparent relapses in cases of stricture of the esophagus which occurred during attacks of pneumonia. The approach to the esophagus in the neck was best made from the left. In his experimental work on the cadaver the so-called extrapleural routes were not promising, and whatever was accomplished would be by the transpleural route, which shortened distances and avoided dead spaces. This was shown by an examination of the mountings.

Dr. W. C. LUSK discussed this communication.

Instrument Table, Sterilizing Drums, and Dressing Boxes.—Dr. H. H. M. LYLE made this exhibition of instruments and apparatus devised for the purpose of expediting work in hospital operating rooms.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held March 28, 1907.

DR. HOWARD C. TAYLOR IN THE CHAIR.

Cyst of Kidney Simulating Ovarian Cyst.—Dr. G. H. BALLERAY presented this and the following specimens: No diagnosis of the condition was made until operation. The patient was thirty years old, and had had one child. When he saw her she had a child seven or eight months old. She had a growth in the abdomen, but it was decided not to operate immediately. Two months later she was operated on and a growth was found that filled the abdominal cavity. It could be felt *per vaginam*. It occupied the median line. When the incision was made the growth had the appearance of an ovarian cyst. When about eight pints of fluid was withdrawn he found that it was impossible to withdraw the cyst by gentle traction. The uterus, tubes, and ovaries were perfectly free. The question of removal of the tumor came up. He removed the secreting surface, cut off the redundant part of the tumor, and brought the surfaces together and stitched them. The woman never had any elevation of temperature, and in three weeks time was sitting up. The interesting point was that the tumor was peculiar in that it was not unilateral, but seemed to be as much on the right as the left side, although the cyst involved the left kidney. As a rule these tumors were unilateral and gave but little difficulty in diagnosis. Even after its removal he was not satisfied but that it might have been a Wolfian cyst. The specific gravity of the fluid was 1.005 and the fluid did not coagulate on the application of heat.

Dr. HOWARD C. TAYLOR said that he had had a case in the hospital which turned out to be a tumor of the kidney and which was taken to be an ovarian cyst when she was first examined. The woman had an endowment bed and was admitted to the medical division, refusing operation. She was on this service for six or eight months and then transferred. She had been tapped six or eight times and more or less fluid had been removed. She was finally induced to submit to operation. She was along in years, seventy years old nearly, and the operation was done hurriedly, removing what was supposed to be an ovarian cyst. The tumor was sent to the pathologist, who sent back word that it was a hydronephroma. This case was of interest because she was under observation so long and had been tapped a number of times. He operated upon what was supposed to have been an ovarian cyst, but the pathologist reported that it was a hydronephroma.

Cyst of Fallopian Tube with Twisted Pedicle.—Dr. Balleray's patient came to the hospital for the purpose of having her perineum repaired, there being a tear through the sphincter, with loss of control over the bowel function. While undergoing preparation for operation, she complained of pain in the pelvis and an examination revealed a small tumor back of the uterus which seemed to press upon the rectum. Before entering the hospital she said she felt something pressing upon the rectum. The pain had somewhat increased. Later the mass became tender and it was then decided to open the abdomen and find what it was. A cyst of the Fallopian tube was found and the pedicle was twisted upon itself. It looked like a dropsical hydatid Morgagni. In all probability a puncture through the vagina would have been all sufficient in this case.

Ruptured Dermoid of the Ovary.—Dr. Balleray saw the patient one week before she was operated on, and, at that time, the tumor reached one and one-half inches above the umbilicus. The increase in size was very rapid; it doubled its size in two months time. On the day she came to the hospital she complained of intense pain and was given a hypodermic of morphine, one-quarter of a grain, which had to be often repeated. Her pulse was 150, temperature 104°. There was vomiting, the face was sunken, the abdomen tender and distended, and her condition seemed to be desperate. She was removed in an ambulance to the hospital, the abdomen was opened, and there was found a ruptured dermoid cyst, with the contents extravasating into the abdominal cavity. It held a quart or more. There was more or less general peritonitis. The tumor, together with the ovary of the other side, was removed. A good recovery followed. The case was of interest in showing how such growths might produce very distressing conditions in such a short time. He thought that probably there was a process of degeneration going on inside the cyst and probably some large vessel was broken into, with hemorrhage into the cavity of the cyst causing its rupture.

Dr. HOWARD C. TAYLOR thought this condition, dermoid of the ovary, must be more or less rare; he had never seen such a case.

Fibroid of Uterus.—Dr. Balleray presented this specimen, not because of any special interest in the tumor itself, but because it gave him an opportunity to say what he had always endeavored to practice or preach, that often one might deviate from the rule of practice. The woman

was forty-three years old, and the tumor had existed for some time. The family physician stated that within the last six months it had doubled in size. The general condition of the woman was not bad. She had a small pulse and suffered from mental depression. She was opposed to any operation. The tumor was such that it blocked the pelvis. There was found one large band extending from the sigmoid flexure and rectum, across, and very adherent to the surface of the tumor. It was attached to the cecum on the other side. The tumor was removed and the recovery was slow, but satisfactory. His contention had always been that when a woman was approaching the menopause, with a fibroid that was not causing pain, or not growing rapidly, she should be left alone.

Adenocarcinoma of the Uterus.—The speaker presented two specimens of adenocarcinoma of the uterus. In both cases the tumor was in the body of the uterus, which was comparatively rare. Carcinoma of the cervix was quite common. There were probably fifty cases of carcinoma of the cervix to one case of carcinoma of the body of the uterus. The two cases presented themselves to him within six weeks of each other. The first case was a woman, fifty-six years old, who ceased to menstruate at forty-five and had been free from any bloody discharge from the vagina since until three months ago, when she had irregular hemorrhages from the vagina. The physician who examined her could find nothing about the cervix. Dr. Balleray examined her and found the uterus enlarged, the cervix normal, and he expressed the opinion that it was probably a case of malignant disease of the body of the uterus. She went away and returned after six months time with the report that she had been bleeding continuously all that time. He removed by curettage a considerable amount of material and sent to the pathologist who reported it to be adenocarcinoma. The uterus was removed and the subsequent progress of the case was not of special interest. The pathologist's report was read. The second case occurred in a woman, forty-three years old. She had menstruated up to one year ago regularly. Then it became irregular. When she was sent to the hospital five weeks ago she had been flowing continuously, but not profusely, for some time. He found the uterus to be somewhat enlarged. Upon examination of the scrapings, and the pathologist's report that it was malignant, an adenocarcinoma of the uterus, the uterus was removed.

Ruptured Tubal Pregnancy.—This woman had not escaped a period when she was seized with severe abdominal pain, and when the physician saw her she was absolutely pulseless. The diagnosis of ruptured ectopic was made and she was removed to the hospital. Her pain occurred at 11 o'clock in the morning; at 6 o'clock she was pulseless and he doubted if anything could be done. At operation the abdomen was found to be filled with blood. The sac was extirpated and all the blood was removed. The abdomen was full of blood, even filling the spaces under the diaphragm and liver, and was found in the flanks. She was flushed with six gallons of water. The morning following the pulse was 112 and could be felt. That afternoon she began to vomit, the abdomen became distended, the vomiting then became continuous, and with a fecal odor, she gradually became worse, and, that evening, the temperature was 104°; at midnight it was 105°, the distention became very marked and she died. Some of the fluid contained the *Bacillus coli communis*. The corpus luteum of pregnancy was found on the side opposite to the rupture.

Dr. Howard C. Taylor said that he did not take the time to wash all the blood out of the abdominal cavity and thought that Dr. Balleray made a mistake in doing this.

Dr. Egbert H. Grandin thought that Dr. Balleray did the right thing. Years ago they tried to remove all the blood from the peritoneal cavity and prolonged the operation. They gradually came to the conclusion that the peritoneum could take care of itself. Dr. Balleray's case, he believed, died from the general toxemia, chiefly intestinal. His technique was in accord with that which was to-day followed by all operators of experience.

Dr. Balleray believed that a certain amount of pure blood did no harm, but bloody serum was different, and was not disposed of so rapidly. Blood or serum did not do much harm; but bloody serum did.

Placenta Prævia.—Dr. Leonard S. Rau read this, the paper of the evening. While it was true that this condition had been recognized and treated as far back as 1685, still to-day it was dreaded, for the results were far from gratifying. Placenta prævia was no longer considered a rare condition, and to-day the proportion was about one case in 500. The statistics depended on whether they were taken from hospitals or private practice. In the former the cases occurred much oftener because these cases were the ones that the practitioners were only too glad to get rid of and to send to the hospitals. Placenta prævia was more common now than formerly and the cause was rather difficult to explain, especially in this country and France, for as he said he would show later, frequent and rapidly following labors were considered among the important etiological factors, but to-day they did not see women who had many children, for it was certainly an exception to deliver a woman who had had more than two or three children. This referred particularly to those who practised among the better classes. Placenta prævia was usually divided into three classes, central (total), partial (lateral), and marginal. The central implantation was the rarest of the three, and some even denied its existence. Of the thirteen cases personally reported to him by Dr. Edgar, four occurred in primiparæ. Of forty cases reported by Dr. Marx, ten were in primiparæ. The lower the implantation of the ovum the more likelihood of a placenta prævia. This implantation might be due either to conditions in the ovum itself (Hofmeier), or changes in the mucous membrane of the uterus. Women doing manual work were prone to placenta prævia partly on account of the work itself and also because the uterus did not have a chance to undergo subinvolution, because of the early rising from bed after delivery and immediately beginning work, and, furthermore, because this was the class of women who had many pregnancies at very short intervals. He offered as an additional etiological factor to explain why placenta prævias were more common to-day than formerly: that the women of to-day so often had abortions performed because they wanted no children shortly after marriage, or else did not want a second one. Consequently they got rid of the products of conception and, as this might happen many times, it explained to his mind why, when they did allow pregnancy to go on to term, the case was likely to be one of placenta prævia. After treating of the symptoms, especially hemorrhage, he considered the diagnosis and said that on several occasions he had been able to make a tentative diagnosis by external examination alone, for he found on inspecting the abdomen a very distinct depression just above the symphysis. The prognosis was always grave for the child; for the woman, it depended upon a number of conditions. It also depended upon the method of delivery adopted. Dr. Edgar sent him a report of thirteen cases with two maternal deaths; Dr. Marx sent a report of forty cases with four maternal deaths. The treatment he divided into expectant and operative. If a woman had slight bleeding in the sixth or seventh month, which yielded at once to rest in bed, she might be left alone with the warning that she must keep very quiet, exercise little, and she should be instructed to send for medical aid as soon as possible if the bleeding again started. If the bleeding continued, one could tampon the vagina tightly and await further developments. In the severer forms of hemorrhage interference became imperative. When the cervix admitted one or two fingers and was easily dilatable, some recommended manual dila-

tation, version or forceps, and immediate delivery. This might favor the prognosis for the child, but it increased the danger to the mother. The temptation to hasten the termination of labor was naturally very great, but personally he did not favor this method. He preferred to introduce a bag, which usually stopped the hemorrhage and caused dilatation. Then, after sufficient dilatation had taken place, he did a version in head or transverse positions, brought down a foot, attached a weight to it, allowed the breach to act as a tampon, and left the delivery to nature. The results to the child might not be as brilliant as in the rapid method, but they were infinitely better for the mother. When this method did not control the hemorrhage one must then terminate the labor by immediate delivery, and, if necessary, pack the uterus after the placenta had come away or been extracted manually. When the cervix was not patulous, rapid dilatation by the Harris or Bossi dilator must be considered. Some preferred cesarean section, vaginal, or abdominal, but it seemed questionable to add to the patient's condition by an abdominal operation, or the difficulty and increased bleeding during a vaginal section. During delivery it might be necessary to stimulate freely, or to do a transfusion or hypodermoclysis, also to give a high enema with whiskey or brandy immediately after the delivery. In every case he gave hot douches, a hypodermic of aseptic ergot, and made his nurse hold the uterus for at least two hours. The after-treatment consisted of prolonged rest in bed, no excitement, etc. The greatest aseptic precautions should be maintained in all cases of placenta prævia, for it was most unfortunate to pull a woman through a difficult labor to have her succumb to sepsis. It was an open question whether they were justified in advising a woman against becoming pregnant again, if she had been safely delivered of a living child, and not allow her to take the chances of another placenta prævia with all the risks that this condition entailed.

Dr. Clifton C. Edgar said he was not in accord with Dr. Rau in his statement regarding the frequency of placenta prævia, for it seemed to him that it was more frequent than one in 500 or 600 cases of confinement. One to 200, or even 175, would not be out of the way. There were many cases of accidental hemorrhage which were really cases of marginal or lateral implantation. As to the etiology, he said he was interested in the statement that it was more frequent in those who had had frequent criminal abortions performed. Personally he knew but little about the etiology except that it occurred more frequently in multiparæ than in primiparæ. He said that Dr. Rau had stated that he was inclined to believe that subinvolution was an etiological factor and occurred more often in the upper than in the lower classes, because of the frequency of abortions among them. Dr. Edgar was not in accord with this view. Among the lower classes there were no reliable statistics to show that they were more prone to placenta prævia than the woman of the higher classes. In the maternity hospital these women refused to remain in as long as they should. Any woman attended by a midwife was usually up and at work inside of a week. With regard to the prognosis, the condition of the cervix determined that to a large extent. The question should be asked: Is the fetus dead? If one could ignore the fetus and confine the attention to the mother alone, a better prognosis would attend. Also, the question should be asked: Is she a primipara or a multipara? Placenta prævia was four times more common in the latter, but in primiparæ the prognosis was infinitely worse than in women who had given birth to several children. These three features in cases of placenta prævia were very important in determining the prognosis, *i.e.* the condition of the cervix, whether the fetus was living or dead, and whether the patient was a multipara or a primipara. Dr. Edgar said he was in accord with what was stated regarding the treatment. But he could not recommend the hydrostatic bags as Dr. Rau did. The more cases of placenta prævia he saw the less aggressive was he as regards treatment. The treatment depended upon that barrier, the cervix. If it was partially dilated he used gauze, which answered two or three purposes; it changed the cervix into a condition which admitted of easy dilatation; it controlled hemorrhage; and lastly, it set up uterine contractions.

Dr. Egbert H. Grandin considered the question of vaginal cesarean section, and said that if one could make a positive diagnosis of placenta prævia at or near term the ideal operation might be cesarean section as offering the child a better chance and not subjecting the mother to greater risk. The diagnosis of placenta prævia was not, as a rule, made until after one or more hemorrhages had occurred; then resorting to cesarean section would possibly nullify the chances of the mother, and might not increase the chances of the child. As to the vaginal cesarean section there was not one logical reason why it should be performed in cases of placenta prævia. In case where it was a marginal or a total implantation, the cervix was certainly dilatable. With regard to treatment, what he had taught twenty-three years ago he taught to-day, and had not changed his method of procedure. He had never used the bags, such as the Barnes' or McLean's modification. He saw no use in the Bossi dilator. Its use often produced what rational surgery aimed to avoid. So soon as the diagnosis of placenta prævia was made the indications were clear, empty the uterus with as much speed as was consistent with maintaining the integrity of the maternal parts. Always consider the life of the mother before that of the child. When the cervix was dilatable, the indication was for the use of one instrument, and that instrument was the hand. Dilate the cervix until the fist could enter, then do a version. For the interest of the child the version should be followed by rapid delivery or extraction. In primiparæ, when the cervix was not dilatable, he still used the gauze tampon, dilating the cervix up to the internal os as much as he could; he packed the cervix full of sterile, not iodoform gauze, and the upper part of the vagina. Then in sixteen or twenty-four hours he anesthetized the patient, removed the gauze, and completed the extraction of the child. The gauze had softened and rendered dilatable the hitherto undilatable cervix, and the complete dilatation could then be done manually, version performed, and a rapid extraction effected.

Dr. S. Marx was entirely in accord with Dr. Rau, although he believed his subdivision was rather a complicated one. He tried to teach a simpler one, dividing placenta prævia into the complete and incomplete. He asked Dr. Rau if he understood him to say that frequent abortions was an etiological factor. He met with more cases among the upper than the lower classes. Placenta prævia was due to too frequent pregnancies and too early getting up. It was the subinvolution which gave rise to placenta prævia. As to prognosis in the forty cases, reports on which he had given to Dr. Rau, the prognosis of the mother was ten per cent. The average number of cases was one to 500. The maternal mortality should be less than ten per cent. If the children were viable every one was born alive. These were the cases he had seen in consultation practice. In over 200 cases in which he had tried to dilate the cervix with the hand he had failed in but five. When one used the Bossi dilator tears would certainly result in the lower uterine zone; tears not only in the cervix, but clear into the broad ligament. He saw no reason for doing a cesarean section pure and simple. In certain pathological conditions, or in those cases associated with a contracted pelvis, for instance, the performance of a cesarean section was indicated, but not for the placenta prævia; it was indicated for the accompanying condition. To-day Dr. Marx said he was less radical than he was years ago; he was now less active and more conservative in the treatment of those cases.

Dr. Joseph B. Cooke said that the matter of diagnosis was one of the easiest things, and that he had frequently made such a diagnosis over the telephone. The mere fact that there was a bright arterial hemorrhage, without pain or apparent cause, was enough to make the diagnosis one of low placenta prævia. He believed that this affection was more frequent than generally supposed, and many so-called miscarriages were in truth cases of placenta prævia. The individual maternal prognosis was good, but for the fetus was bad; the fetus was usually a premature one. Frequently there was a malposition, or a malpresentation, because the placenta was low in the pelvis and the child could not assume its proper normal position. As to safeguarding the fetus the mother's life should be considered before that of the fetus. He believed that placenta prævia was as much an ectopic pregnancy as was a tubal pregnancy, and the duty was to ignore the fetus and deliver the mother. After delivery he invariably packed the uterus because of the possible bleeding from the lower uterine sinuses.

Dr. Rau closed the discussion. He said he was opposed to the cesarean section, through either the abdomen or the vagina. He had had no experience with the Bossi dilator to any extent. For many years he had used the method of manual dilatation and rapid extraction of the child, but only lately had he become afraid of that method; such a method subjected the mother to greater risk, the risk of a severe tear. As to bright, red blood in the diagnosis of placenta prævia, this occurred also in cases of premature detachment of the placenta, and this was not a placenta prævia.

Dr. Cooke replied that what he said was "bright arterial blood, without pain or apparent cause."

Dr. Edgar said he intended to say that the Bossi dilator had a place in the treatment of these cases.

Pathological Society of Philadelphia.

At a stated meeting held April 10, Dr. B. A. Thomas exhibited two specimens of gangrene of the foot, one of which was secondary to thrombosis of the popliteal artery and the other to proliferative endarteritis. The first specimen was obtained by amputation from a man in whom the operation of Matas for the relief of a femoral aneurysm was performed. The second specimen was obtained following surgical removal for the relief of the results of vascular occlusion due to senile endarteritis. Recovery ensued in both instances. Dr. Joseph McFarland presented a specimen of multiple echinococcus cyst of the gluteus maximus muscle. The cyst was obtained in the dissecting room from the body of a colored woman between thirty and forty years old, concerning whom the only thing that could be learned was that she was a native born American. Many daughter-cysts were present but hooklets could not be found. Dr. Alfred Gordon presented a specimen of tuberculoma of the spinal cord. The patient had been a colored individual who had presented paralysis of three extremities, with paresis of the fourth, and abolition of the reflexes, but for the last few weeks of life entirely free from pain. After death a tumor was discovered arising from the seventh cervical vertebra and invading the dura and pia and the cord. In addition to the direct involvement of the cord there was the usual ascending and descending degeneration. Histological examination disclosed the structure of a tuberculoma. Dr. Aller G. Ellis presented a communication entitled "Accessory Pancreas." He referred to the relative rarity of this condition and he reported two cases under his personal observation. In one of these the supernumerary structure was situated in the hilus of the spleen and in the other within the walls of the stomach. The latter pancreas was undergoing adenocarcinomatous transformation. Dr. Leo Loeb read a communication entitled "Further Observations on the Endemic Occurrence of Cancer, and on the Inoculability of Tumors." He presented a judicial analysis of the reports that have been made as to the etiology and inoculability of malignant growths, and he cited observations of his own made during a period of eight years or more. He pointed out that certain animals exhibit a definite susceptibility to certain forms of new growth, both spontaneously and by inoculation, and he showed how some degree of immunity and some therapeutic effect could be brought about by inoculation and by other means. He thought that there must be something in the character of the growth and something inherent in the subject that determined the question of inoculability He had no final opinion as to the fundamental etiological factor in malignant diseases. For him the entire subject must be studied from the purely biological standpoint, and any practical results from such a study must be awaited with patience. Dr. John B. Deaver said that, as a surgeon, he took all precautions against inoculation and infection in operating on cases of malignant disease. Dr. Allen J. Smith contended that it was not necessary to look for extraneous parasites in a study of the etiology of malignant disease, but that this may be found to reside in the cells of the neoplasm itself. Dr. Ernest Laplace discussed the part played by the *Micrococcus ncoformans* in the etiology of carcinoma and the utility of a serum obtained from cultures of that microorganism. In his own experience he had obtained only negative results from the employment of the serum. Dr. Jos. McFarland pointed out that the question of the inoculability of carcinoma has already been discussed for many years. He spoke of various observations on this subject and said that his own studies had led him to believe that transplantation from one person or animal to a healthy person or animal is not common and that the existence of a new growth rather predisposes to the readiness of reinoculation, accidental or experimental.

Philadelphia County Medical Society.

At a stated meeting held April 10, Dr. Chas. W. Burr presented a communication entitled "Paranoia: Its Varieties and Medicolegal Importance." He pointed out the difficulties in the way of a satisfactory classification of the different forms of insanity and showed the great diversity of opinion as to the exact limitations of the disorder designated paranoia. He contended that insanity results from forces operating without the body of the affected individual or arising from inherent conditions, and especially hereditary influences. The paranoiac is the descendant of an abnormal ancestor. His striking feature is his pronounced egotism. He considers himself different from and superior to his fellows, and he is likely to be boastful and vainglorious. He is, moreover, extremely suspicious. He is deficient in moral sense and is likely to be a sexual pervert. His promises and his hopes fail of realization and his career is always one of unsuccess. He may appear to possess good reasoning power, but his premises often are false. At times the disorder is so little marked as to escape detection at a single observation, but more protracted and more frequent scrutiny will disclose the earmarks of the disease. Dr. Robert H. Chase read a paper entitled "Insanity: A Defense in Homicide." In order to obviate the conflict of expert testimony so frequently observed in trials for murder, Dr. Chase suggested the appointment of a State Board or committee to pass upon the qualifications and fitness of would-be experts in insanity. Dr. Chas. K. Mills contended that under prevailing conditions it is doubtful if any deviation from the present method of presenting expert evidence would be an actual improvement. Dr. Francis X. Dercum emphasized the distinction between paranoia and paranoid states. The discussion was further participated in by Drs. John B. Chapin and Alfred Gordon, who spoke of the problems involved in the classification of insanity from the forensic standpoint.

Medical Jurisprudence Society of Philadelphia.

At a stated meeting held April 12, Dr. Arnold Lorand of Carlsbad, by invitation, presented a communication entitled "The Pathogeny of Crime." He considers crime a manifestation of disease, and will power and facility of reasoning the two most important means for its prevention in the individual case. These forces become impaired in connection with disorders in the function of the ductless glands. He dwelt on the mental symptoms attendant on myxedema and exophthalmic goiter, disorders dependent on diseases of the thyroid gland. He contended that criminal judges should be assisted by sworn experts in diseases of the nervous system, employed neither by the defense nor by the prosecuting attorney, but by the government. Religious fervor reaching to the height of superstition is one of the causes of crime. Christian Science is such a superstition, leading to manslaughter by negligence. A great curse is the idleness of the children of the rich. Criminals should be treated as if diseased mentally, and they should be placed at hard work, preferably in the open air.

The Treatment of Acute Suppurative Conditions by Bier's Method.—Kaefer praises Bier's congestion method very highly, and states that he has found it of value in a great variety of inflammatory conditions. One application of the principle of hyperemia to which he attaches great value is in the treatment of operation wounds. At the first signs of infection, such as redness or pain, the hyperemia is induced, by bandaging if an extremity is involved, or by suction apparatus if the wound is on the trunk, instead of following the customary plan of removing the stitches. The latter procedure usually can be avoided entirely in this way and the threatened infection be staved off so that healing by first intention is secured. The plan has been found especially useful in dealing with amputations of fingers on the necessarily very dirty hands of factory operatives.—*Zentralblatt für Chirurgie.*

Congenital Malformations and Transposition of the Viscera.—Garrod and Langmead have recently had this case under their care. The patient was a girl nine months old. She was brought to the hospital suffering from severe constipation. Her general condition was poor. On the day following birth she was operated on for imperforate anus. The child had the appearance of an idiot of the Mongolian type. Physical examination showed that the heart was on the right and the liver on the left side. This was confirmed by the *x*-ray. Autopsy showed that the heart was not only displaced, but that it was also deformed. There was persistence of Botallo's foramen, the interventricular septum was incomplete, and the arterial channel was permeable. The superior lobe of the right lung was absent. Garrod has often remarked the coincidence of the transposition of viscera with malformations, and a special conformation of the head relating to the Mongolian type.—*La Presse Médicale.*

Uterine Inversion.—Pinard reports the case of a multipara who was delivered with forceps. Uterine inversion followed, which was reduced by the hand of the accoucheur. The fourth day, as the patient was at stool, the inversion occurred again. At this time a Champetier de Ribes bag was applied and the uterus was replaced. Pinard insists upon the rarity of spontaneous uterine inversion. This condition is most often due to violent tractions on the cord. Nevertheless there are other causes. A case was observed by Queirel in which the placenta was inserted on the fundus of the uterus. At other times this catastrophe occurs from uterine inertia, which is sometimes primary and sometimes secondary. In recent cases reposition may generally be obtained by the hand of the physician. In cases not amenable to this treatment the Champetier de Ribes bag is a wonderful instrument.—*Le Bulletin Médical.*

Books Received.

While the Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Einführung in die Gerichtliche Medizin für Praktische Kriminalisten. Vier Vorträge von Dr. Hugo Marx. 8vo, 129 pages, illustrated, paper. Berlin, 1907, Verlag von August Hirschwald.

A Compend on Bacteriology. By Robert L. Pitfield, M.D. 12mo, 232 pages, illustrated, muslin. P. Blakiston's Son & Co., Philadelphia.

Essentials of Obstetrics. By Charles Jewett, A.M., M.D., Sc.D. Third edition, revised and enlarged, 8vo, 413 pages, illustrated, muslin. Lea Brothers & Co., New York.

A Pocket Formulary. By E. Quin Thornton, M.D. Eighth edition, revised, 16mo, 287 pages, flexible leather Lea Brothers & Co., New York.

Medical Diagnosis, A Manual for Students and Practitioners. By Charles Lyman Greene, M.D. 12mo, 683 pages, illustrated. P. Blakiston's Son & Co., Philadelphia. Price, $3.50 Flexible leather.

A Study of the Human Blood-Vessels. By Arthur V. Meigs, M.D., 8vo, 136 pages, illustrated, muslin. J. B. Lippincott Co., Philadelphia.

Diseases of the Lungs. By Robert H. Babcock, A.M., M.D. First edition, 8vo, 809 pages, illustrated, muslin. D. Appleton & Co. Price, $6.

This Labyrinthine Life. By George Alexander Fischer. 12mo, 382 pages, illustrated, muslin. B. W. Dodge & Co., New York.

New Instruments.

A NEW GAS-ETHER INHALER.

By HENRY DAWSON FURNISS, M.D.,

NEW YORK,

INSTRUCTOR IN GYNECOLOGY, NEW YORK POST GRADUATE SCHOOL AND HOSPITAL.

THE instrument consists of three portions: neck piece, to which the rubber bag for the nitrous oxide is attached; the ether chamber, and the face piece.

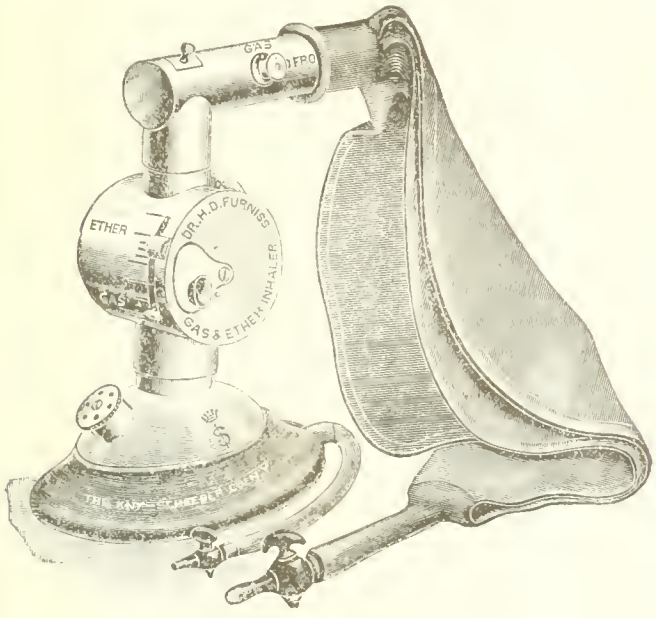

FIG. 1.

The neck piece is so constructed that when the slot on the top is open the passage to the gas bag is closed by a window shutter. Distal to this is a valve on a seat like the damper to a stove. This valve opens on inspiration, closes on expiration, and is out of play when the valve seat is thrown into the long

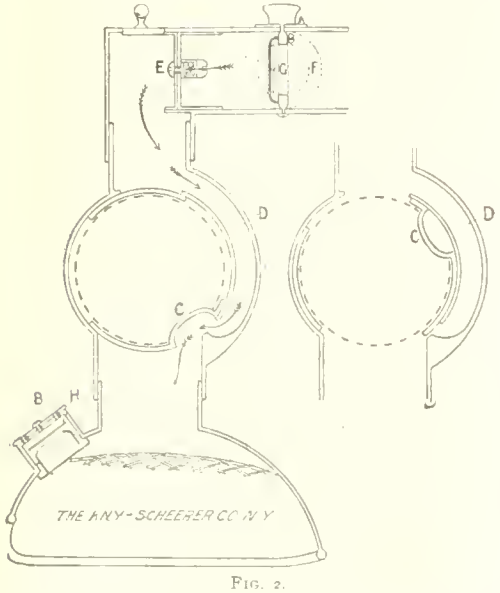

FIG. 2.

axis of the tube by turning the pointer to "to and fro." When the valve is not working air passes freely in either direction.

The ether chamber consists of two portions, the one fitting within the other, and revolving through about 60°. They are locked together by means of a pin that passes under a collar into the slot cut in the outer portion of the inhaler. For this fastening arrangement I am indebted to Mr. Sorensen of the Kny-Sheerer Company. Reference to the outline cut will show the construction better than any words. The figure to the left shows the instrument in the position for gas inhalation; that to the right when it is set for ether. It is clearly seen how the gas is conducted around the side of the inhaler by means of the tube "D." "C" is a metal cap soldered over an opening cut in the inner revolving portion of the ether chamber. The dotted line represents a wire cage, which is so constructed that it is separated from the wall of the inhaler one-eighth inch to allow of the free passage of air around it. This cage is to be packed with gauze or sponge. The cap on the side of the inhaler is for the opening and closing of the hole through which ether is to be poured on the gauze.

The face piece has a valve that opens on expiration, closes on inspiration, and which is out of commission when the fenestrated cap covering it is closed. When this valve and the one on the neck piece are both in play the patient receives undiluted gas; when both are thrown out the patient breathes to and fro into the rubber bag. Across the middle of the face piece is placed a wire screen, the use of which is given below.

The connections between the different portions of the inhaler are made by slip joints, which is easier to manipulate, less liable to injury, and just as efficient as screw joints. The neck piece is so constructed that it can be joined directly to the face piece when it is desired to administer nitrous oxide alone, all the necessary valves being contained in these two portions.

It was due to the inability to keep some robust individuals under the influence of ether with one of the popular gas-ether inhalers that this inhaler was devised. The defect to be overcome was the inadequate capacity of the ether chamber. Realizing that this would have to be overcome by ridding the inhaler of any tubes passing through it, the idea of having the gas passage on the outside was hit upon. This advantage made possible another, a very large opening into the bottom of the ether chamber, which

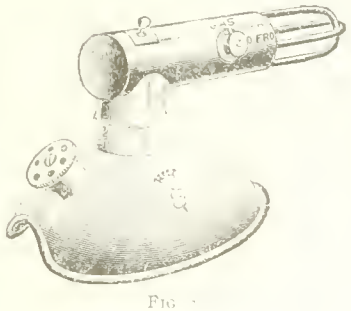

FIG. [illegible]

in this inhaler has an area three times as great as that of some of the most popular models now offered the profession. These improvements have been made without complicating, but rather simplifying the instrument.

The space above the wire screen in the face piece can be packed with gauze or sponge when it is desired to use this as auxiliary ether space, or when the drop method of administration is desired. This part of the instrument also makes a very desirable chloroform mask.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious disease reported to the Sanitary Bureau, Health Department, New York City, for the weeks ending April 20 and 27, 1907:

	Week of April 20		Week of April 27	
	Cases	Deaths	Cases	Deaths
Tuberculosis Pulmonalis	401	210	407	227
Diphtheria	331	45	339	39
Measles	411	8	477	17
Scarlet Fever	478	27	534	26
Smallpox	2	—	1	1
Varicella	64	—	96	—
Typhoid Fever	100	13	100	18
Whooping Cough	66	11	60	11
Cerebrospinal Meningitis	15	20	20	17
Malarial Fever	..	..	..	..
Totals	1868	320	2034	350

Phlebosclerosis.—Agostino Carducci has studied the occurrence of sclerosis of the veins and the clinical symptoms arising from the condition in eighteen cases, of which he gives us the histories. These changes in the veins are manifested by diminution in the caliber of the vein and absence of any coagulations in the vessels. There is a proliferation of the intima without any tendency to regressive alterations. It is more frequent in the subjects of arteriosclerosis, tuberculosis, malignant tumors, and malarial cachexia. There is no definite knowledge of the pathogenesis of this condition. It has no particular symptomatic syndromes, the functional results being inconstant. It may be diagnosed when it attacks the superficial veins, but not in the deep veins. It must be diagnosticated from spasm of the veins and from thrombosis. Prognosis is good, and treatment is unknown.—*Il Policlinico.*

Significance of Hypothermia with Slow Pulse in the Puerperium.—C. Merletti has studied the pulse curve in about a thousand cases in the puerperium and has observed that whenever there is an infective process of the genitals, no matter what the location or the severity of the process, the pulse rate rises in proportion to the rise of temperature. On the other hand there are cases in which with a rise of temperature there is no increase of pulse rate, or it is even lower than normal; in none of these cases is there any sign of genital affection, and the fever goes down without any treatment for the genitals. There is also no alteration in quality, such as dichrotism, in these cases, as is found in ordinary febrile affections. Such fevers are due to gastrointestinal troubles, intercurrent diseases, anomalies of lactation, or of the lochia, nervous conditions, etc. The practical deduction from these facts is that in cases in which with the rise of fever the pulse remains normal we should abstain from treatment of the genitals.—*La Riforma Medica.*

The Prevention of Puerperal Mastitis.—Döderlein states that a solution of india rubber in benzine, to which 1 per cent. of formalin is added, can be used as a local application to prevent the formation of minute fissures about the nipples of nursing women. The entire nipple is painted with this solution and as soon as the benzine evaporates a little sterile talcum powder is sprinkled over the area treated. In this way a delicate membrane is formed which occludes the lacteal ducts, but the first time the infant nurses the act of suction perforates the thin layer of rubber over the mouth of each duct. The nipple remains protected against all infection or abrasion, however, and in the 200 cases in which Döderlein has employed the method he has found it an extremely valuable prophylactic against mastitis. The applications are repeated every two or three days and by this means it is stated that the discomfort of nursing due to tender nipples is very greatly alleviated.—*Centralblatt für Gynäkologie.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended April 26, 1907:

A DISTURBANCE OF VISION DUE TO EXAGGERATION OF BINOCULAR ASSOCIATION.*

By PIERRE JANET, M.D.,

PARIS

PROFESSOR OF PSYCHOLOGY IN THE UNIVERSITY OF FRANCE.

In replying to the courteous invitation of the New York Neurological Society, by which I feel myself greatly honored, I wish to present briefly a rather curious case which, in my opinion, shows well the value of the study of pathological psychology for the understanding and oftentimes for the treatment of nervous diseases.† First allow me to review the previous history of the patient, without which it would not be possible to understand the particular condition which we wish to study.

The patient, Mme. Z., now sixty-five years of age, has always been a very neurasthenic person. She has shown during her entire life a series of manifestations of a characteristically hysterical nature. Overwhelmed at the age of fourteen years by a violent shock following the accidental death of her sister, she lost the use of her limbs and remained paralyzed for a year. Since that time she has had, successively or simultaneously, hysterical attacks with catalepsy, disturbances of speech, contraction of the neck, spasms of the right arm, various pains affecting the fingers, the nape of the neck, the tongue, and varied paralyses. The last well-defined occurrences of this kind took place at about the age of fifty years. At that time she still had some slight crises of uncontrollable logorrhea, a last remnant of the old somnambulism. Since that time the strictly hysterical conditions have yielded to phenomena of another nature of which we need not here discuss the pathogeny.

Three years ago, after some pronounced symptoms, she was attacked by disseminated retinal hemorrhages in both eyes. At the close of a few weeks the hemorrhage, which had not been very severe on that side, had entirely disappeared in the right eye, leaving, as Dr. Valude had reported, only some points of insignificant sclerosis in the outer part of the retina incapable of disturbing vision. On the other hand, the ophthalmologist noticed from the outset very abundant punctiform hemorrhages in the left eye, with marked localization near the macula. As a result the left eye recovered only a little visual power, but for a short time, and that was definitely effaced by the progress of sclerosis, so much so that at the end of two months the vision was completely lost in the left eye and almost wholly restored in the right eye. At that time, however, disturbances began which progressed continuously. The patient complained of experiencing in her left eye phenomena of light—"streaks of fire, flashes, Roman candles," and these flashes were accompanied by violent pains which gradually developed to an incredible degree. This intolerable condition lasted more than a year. Finally, in a consultation between Dr. Valude and Dr. Dufour of Lousanne it was decided that the absolutely useless left eye ought to be sacrificed, since it had not the slightest vision and was only a cause of optic nerve irritation. Enucleation, which the patient did not wish at any cost, did not seem indispensable, and it was decided to limit our interference to section of the optic nerve, an operation which had already been advised by von Graefe in like circumstances. The operation was performed by Dr. Valude and was successful. When the dressings were removed it was seen that the left eye had admirably preserved its vitality and presented an absolutely normal appearance. However, the movements of the eye were seriously disturbed. To reach the optic nerve one is obliged to section the external rectus, which is sutured after the operation. Perhaps the point of the scissors slightly cut the internal rectus. After the operation the eye rotated strongly to the outer angle. Later it took on more motion and could turn strongly to the right side, when the patient made an effort, but even then the movements were not entirely recovered, and there remained a certain amount of divergent strabismus. The right eye had suffered not at all, either from the operation or its results. When the dressings were removed, it was found to be normal, and a cursory examination showed that vision was preserved. The visual acuity was good, the field of vision was very wide, almost normal, scarcely affected by the original hemorrhage, and colors were well distinguished. It was thought that the patient could henceforth use that eye and, being no longer troubled by pains in the left eye, would see correctly.

But now commenced the peculiar disturbance of vision which developed following the operation and which has given rise to my psychological researches. Mme. Z. saw correctly at the first glance, but she complained that she was unable to profit by that vision, for she said that there was before her a strange cloud, always in motion, which hid from her the appearance of the objects looked at. In vain she made every effort to fix an object, to follow a line. The vision was disturbed by this moving cloud and it was impossible for her to see anything with accuracy. Not only was reading impossible, but the vision of objects in the room was so difficult that the patient had trouble in moving about. Moreover, this moving cloud soon caused vertigo and nausea, so much so that to recover her normal condition it was necessary to close the eyes. In a word, the patient was without doubt delivered from pains which had tortured her previously, but she complained of not having made any progress, for

*Read before the New York Neurological Society, November 28, 1906.

†The more complete details of the eye conditions of this patient were published in the *Annales d'Oculistique*, July, 1903. I have here dwelt only upon the interesting psychological manifestations.

she considered herself still more incapable of helping herself with her right eye. These peculiar troubles continued to increase for almost a year without any apparent progress, and the despondency of this very neurasthenic patient still further aggravated her previous troubles.

Evidently phenomena of this kind deserve to be called nervous disorders of vision and, given the symptoms which the patient had presented up to the age of fifty, one would naturally speak of a hysterical condition. However, it is scarcely possible to admit ordinary hysterical amblyopia, when one recalls that the vision of the right eye seemed normal at the time of the medical examination, that its acuity is almost normal, that there is no disturbance of color vision, that the visual field is almost as extended as that of a normal eye. Any existing hysterical disorder must be of a very peculiar nature. In order to discover the trouble it is necessary to analyze the circumstances in which vision is especially found to be altered, and the conditions if such exist, in which the trouble diminishes and in which vision is found to be momentarily restored. Vision is preserved only at the first instant under one condition; it is that the patient limits herself to describing the object placed before her, whatever it may be, without herself choosing it. As soon as she attempts to fix any thing or to accommodate, the trouble begins. Mme. Z. is able to read letters or words off-hand in a book opened before her, but everything is immediately invaded by the brilliant cloud. If she seeks to follow a line with her eyes, the more she attempts to look with fixedness and attention the more the visual troubles appear to increase. The circumstances which directly or by association evoke the superior functions of vision are the occasion of the visual trouble.

On the other hand, it is necessary to note a rather large number of somewhat peculiar conditions under which the trouble, if not suppressed, is at least reduced. It was observed that at the instant of opening the eyes vague vision, without choice and without fixation effort, was fairly well preserved. In the morning at the moment of waking, while she was still half asleep, Mme. Z. noticed that she saw well. A peculiar lighting, a chance position, sometimes brings on a sudden change and for some moments she is astonished to see as heretofore, but that vision is short, and the patient does not know what to do to recover it. She seems to have observed that it is necessary to receive the light upon the left side of the face in such a manner that the shadow of her nose, which is rather large, completely protects her right eye. She desires a very tight bandage over her left eye or she tries to press it strongly with her fingers, but as soon as the eye escapes and begins to move again a mass of brilliant clouds comes to obscure the visual field. These few observations seemed to show that the right eye was capable of seeing whenever it was disassociated from the left eye and that the intervention of the left eye, although blind, was the origin of the trouble. To verify this I tried some experiments in which the monocular vision of the right eye was brought out still more clearly. Here is a peculiar one. Mme. Z. was formerly accustomed to shoot with a pistol and could aim with the right eye. I have asked her in holding the pistol, or even a simple piece of wood, to repeat the effort of aiming. To her great surprise she then saw perfectly well the object aimed at, without clouds, etc. In another experiment I made her look through a field glass and she then saw objects at a distance perfectly. I took a microscope to her and she was able to use it and describe preparations. At last I made her look simply through tubes of paper and by this very simple means she became able to read without difficulty. Hence we have a collection of facts which seem to show us that the trouble in sight disappears when we suppress the association of the two eyes.

How are the preceding phenomena to be interpreted? Here is an explanation that I offer you for at least a working hypothesis. It is said that there exist in man two different visions, binocular vision with convergence, and monocular vision in which the two eyes functionate independently of each other, but one is not disposed to speak ordinarily of these two visions when there exists but a single eye. At first one thinks that a one-eyed person can have only monocular vision. This is probably true for those who lose an eye in early infancy, but those who become blind as adults preserve the cerebral mechanism of binocular vision in all conditions in which that vision is used ordinarily, and they use only the cerebral mechanism of monocular vision in unusual conditions. Ordinarily the preservation of that association of the two eyes scarcely annoys them, perhaps because the subject troubles himself little about the incorrect movements of the blind eye. It is likely that Mme. Z., in spite of the section of her left optic nerve, every time that she is wide awake, or that she pays attention, or that she attempts to follow a line, still tries to use binocular vision. She still attempts to make the two eyes converge, to accommodate both in the same manner, and she does not limit herself in doing the work of fixation and accommodation to the right eye only.

What is the cause of this obstinacy, as it were, in using binocular vision in spite of the loss of one eye? One might say at first that it is one of the fixed ideas, or, if one chooses, one of those fixed psychological states such as we see continually in the hysterical. It may be added that Mme. Z., old and neurasthenic, is less able than another to change her visual habits and to adapt herself to a new situation which demands a new action of her visual perception. This is the one important reason why the patient perseveres in her search after binocular vision. Binocular vision, however, has become entirely impossible, for not only is the left eye blind, but the movements themselves cannot be accomplished as in the right eye. It has been seen that the operation has left a divergent strabismus. It has also been noted that the pupil, which has only slight mobility, does not give correctly the consensual reflex. I am disposed to believe that it is this consciousness, more or less confused by the defect of convergence and by the defect of accommodation in the left eye, which, in a subject who is very neurasthenic and obstinate in seeking to obtain an impossible binocular vision, causes trouble in the fixation and accommodation of the right eye.

Some therapeutic experiments bring an interesting verification of these hypotheses regarding the pathogeny. I have attempted to submit the patient to a reeducation of vision by taking as a point of departure, as one must do in these reeducations, that part of the function still remaining. Here the vision remaining is the monocular vision under certain definite conditions. I wished to force the patient to develop monocular vision by placing her under conditions which called for it. I had made for Mme. Z. a pair of peculiar glasses. Upon the frame of the right eye was set a little metallic tube as large as the orbit and five centimeters in depth. Through

this tube the patient easily obtained distinct vision. When she became a little more used to it, I had the depth of the tube reduced, as it became unnecessary in the outer part, until it had a depth of not more than a centimeter and a half in the inner part. Thus reduced, the tube did not necessarily give monocular vision, but it acted as a stimulus to cause favorable conditions to obtain that vision which was already used in the tube of a field glass or in aiming with a pistol. This very short tube, or rather this little rim, placed in the inner angle of the eye suffices not only for the patient to guide herself, but for her to read easily for more than an hour.

I hope that, little by little, in spite of the age of the patient and in spite of her neurasthenic past, the habit of monocular vision may develop and that it may even take place in the absence of all special apparatus.

The treatment of nervous troubles, as has been said, very often consists in reeducation, but it is necessary to determine accurately through psychological analysis the factor on which this reeducation must work.

APPENDICITIS IN INFANTS AND CHILDREN.*

WITH A STATISTICAL ABSTRACT OF ONE HUNDRED CASES OPERATED ON IN FIVE YEARS.

By JOHN F. ERDMANN, M.D.

NEW YORK.

CLINICAL PROFESSOR OF SURGERY, UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE.

THE difficulties in making a diagnosis of appendicitis in occasional adult patients, even with all scientific aids added to a well-developed history, are greatly multiplied in infants and children who are unable to express themselves, or in whom there is, from a sense of fear, a distinct reticence in giving up such factors as are great aids in reaching a satisfactory conclusion. In addition, in infants the many gastrointestinal complaints which they may be subject to cloud our reasoning, and thereby delay our diagnosis.

Of the factors in obscuring our diagnostic acumen are the teachings that meats, etc., substances of diet that the young and adult take, are causative factors in the production of this disease, and therefore that a milk baby cannot have it, and that an appendicitis is an exception in certain tribes of the Orient who subsist on vegetation only. Such teachings, especially when given by observers of note, must of necessity place appendicitis in infants (milk-fed subjects) as a rarity rather than as an occasional disease. Nevertheless, this disease does exist in the milk and prepared food infants frequently enough to give us cause for alarm when seeing infants or children under three years of age suffering from abdominal pains, distention, etc.

Kermisson, in the *Revue de Chirurgie*, p. 2042, 1906, abstracted in the *Journal of the American Medical Association*, December 22, 1906, reports a case in an infant eleven months old, and says he has found reports of twenty-five under two years, nine of which were under twelve months. Of this number (twenty-six) nineteen died and seven recovered, appendectomy having been done in nineteen cases, with a mortality of twelve, seven deaths being in those under twelve months. Conclusions cannot be drawn from this great mortality, as he further states that only those operated upon at once recovered.

I have recently operated on a patient twenty-one months old, in the second day of the disease, finding a concretion one and a half inches long by about three-fourths of an inch wide in a perforated and gangrenous appendix, with general suppurative peritonitis, with a fatal termination in twenty-six hours.

One thing is apparent, and that is the rapidity of intoxication due to the spreading of the peritoneal invasion in these cases, and the marked lessening of resistance in the patients under three years.

Kermisson further states that no meat had been given in any one of the cases cited in his paper, and thereby disposes to a great degree of the argument that meat is a factor in the production of the disease; but he also states that in twelve of the cases in which the particulars were known all except three were bottle babies. It would appear to me that at present we cannot lay stress upon any particular food articles as being productive of this disease, and whether food preservatives, such as boric acid, etc., have any weight in the consideration of the cause, I am not prepared to say.

To diminish the great mortality in appendicitis occurring in infants under three years, we must first recognize that this disease is an established fact, even in breast-fed babies. Then we must improve our diagnostic sense by summarizing such symptoms in infants as have been shown to be accompanied by appendicitis, and finally to insist upon early operation as we do in adults.

It is a recognized fact by all that this disease may be insidious in onset, and is rapid in its progress as to spreading, loss of resistance, and toxemia, The time of descent of the cecum with its appendix must be recognized, for frequently the appendix is not in the abnormal site before the third or fourth year, but lies high up, even under the costal arch, and therefore in these cases palpation with elicitation of pain in the usual site is negative, while palpation in the loin or high up may be productive of the sign we are seeking. The same may be said of the localization with mass formation. I have frequently, in the series abstracted in this paper, been compelled to remove the appendix almost at the lower border of the costal arch.

In arriving at a diagnosis we must consider gastroenteritis, invagination, and obstruction due to hernia, etc.

In gastroenteritis the symptoms dovetail so thoroughly in many instances with those of appendicitis as to prevent a diagnosis being made before one of the evidences, such as peritonitis, obstruction, or mass, be present. In invagination one might mistake the tumor, which is usually symmetrical when present, for an inflammatory mass, but the bloody and mucous stools, the peculiar rhythmic cramp-like pains, and a degree of shock not seen in appendicitis, all should be sufficient to make a correct diagnosis possible. In hernias the external lesion is usually present, whereas, if it be a concealed hernia, it would be a rare diagnostician who could make a proper differentiation.

Symptoms.—Pain, with nausea and vomiting either preceding or accompanying, and with following temperature elevation, increased pulse, difference in the sense of resistance in the abdominal wall, distention in varying degree, crying of the

*Read before the East Side Physicians' Association, New York City, February 15, 1907; and the Bridgeport Medical Association, Bridgeport, Conn., March 5, 1907.

child upon palpating the abdomen, fitful crying and sleep. The patients, in the majority of instances, ward off the examining hand. In an article on appendicitis in children (*New York Medical Journal*, March, 1904) I called attention to the above sign, stating that to me it is almost pathognomonic, as follows: "Almost invariably the little patients unconsciously place their hands in the region of the appendix to ward off manipulation in this region."

Rectal palpation rarely is an aid in these cases. The blood count does not help when the question is between a low placed pneumonia and an appendicitis. The same applies to the painful area in low placed pneumonia or diaphragmatic pleurisy. In these latter diseases the movements of the costal arch in respiration must be carefully watched.

I have found pinworms as foreign bodies in ten patients, and in almost every instance the symptoms were the same, and peculiar to the general cases. There is pain, with temperature of 104° to 105° for twenty-four hours, then a subsidence in temperature to 99.5° to 100.5°, and the pulse not accelerated; pain diminished but present; and then in the following day or two an elevation of temperature of a degree or two, without marked increase of pain.

The removed appendix is seen to be slightly congested, and the interior distinctly so, with perhaps one or more macroscopic spots of epithelial destruction, and pinworms varying in number.

Intercurrent Conditions.—I have operated twice in cases of floating kidney, one on a girl eleven years old, and recently on a boy fifteen years old, and have seen a third, a girl of fourteen, with a marked history of mild attacks, having a kidney almost in the iliac fossa.

There was right inguinal hernia in three cases, the operation for both conditions done through the hernial incision. One of these cases was in a male child, one year old, who had a strangulated hernia, and an inflamed appendix.

Pertussis occurred in one case, that of a boy of seven years; gangrenous appendix; no drain; recovery.

One patient with an acute fulminating attack was exposed to the sun, and a long, tedious train journey, on a hot day in August, 1905, and suffered for three days all the symptoms of an insolation.

Strangulated ovarian cyst occurred in a girl thirteen years old, with recovery.

Pyosalpingitis, gonorrheal in origin, was noted in one child five and a half years old, from whom I removed the appendix thoroughly incorporated with a pelvic abscess and right pyosalpinx; also with a distinct tuboovarian abscess of the left side. The patient recovered.

No consideration in this series is made as to the time of seeing cases, as all but five were acute.

The postoperative complications, barring those of intestinal paresis from spreading peritonitis, were in this series of cases pneumonia and subphrenic abscess. Two of the deaths recorded were due to pneumonia, and one to subphrenic abscess and exhaustion at the end of the sixth week. This latter was the case in which marked evidences of insolation were present for three days. One other case of subphrenic pleurisy recovered.

The total number of cases operated upon by me from January, 1902, was 100, of which 41 had foreign bodies, including 10 with pinworms. Twenty-four had perforated, with or without general gangrene; 50 were gangrenous, with or without perforation and pus. Thirty out of 78 seen since January, 1904, had pus, either localized or general, and with or without gangrene and perforation, while only 5 were interval cases. Thirty-seven cases were drained.

Of the 60 cases operated upon in which the sex is recorded in my file, 35 were male and 25 were female.

Ninety-five cases operated upon in which I have the actual age recorded occurred in the following numbers, as to years: One at 1 year, one at 21 months, one at 2 years, three at 3 years, seven at 5 years, four at 6 years, ten at 7 years, seven at 8 years, eight at 9 years, nine at 10 years, fourteen at 11 years, eleven at 12 years, five at 13 years, four at 14 years, and ten at 15 years.

There were seven deaths in this series, a percentage of seven. The following were the causes of death: Pneumonia, two; subphrenic abscess, exhaustion, etc., one; general suppurative peritonitis, four. The children dying of general suppurative peritonitis were aged 10 years, 21 months and 11½ years respectively; the age of the fourth was not given. All were in a most profound septic condition; one, 10 years old, dying within ten hours; the infant in twenty-six hours, and the 11 1-2 year child, a boy ill seven days, who was cyanotic, etc., with an abdomen distended, as the two others had been, dying in about eight hours. Records in the fourth case are not definite.

While these four cases presented conditions of profound gravity, I cannot but feel that if any chance was to be given them it was that of operating rapidly, with little or no great contusion of the abdominal contents being made, and then followed by the Murphy-Fowler-Ochsner treatment.

Although these steps were carefully carried out, and the result no better than if no operative procedure had been instituted, a sufficient number of cases similar in nature but not in intensity having recovered, would still cause me to operate in like instances.

Treatment.—I am a firm believer that once an appendicitis has occurred the patient is always in danger until the organ is removed, and I advise that the patient seen in all such cases be submitted to operation.

The usual preliminary steps that can be taken in emergency operations should be followed. The incision is either that of McBurney or Kammerer, or that which splits the rectus, no matter whether we feel that drainage is likely to be necessary or not. The McBurney is done when no mass can be felt, or when the mass is well confined to the iliac fossæ, while the Kammerer or split rectus is used in those cases where the mass lies more to the median line, or down in the region of the bladder.

The incision when first made is never over two inches long, and is more than likely to be that of Morris, one to one and a half inches in length. As a rule I use no gauze protecting dam, but make a very careful finger dissection, recognizing readily when the rupture of the abscess, if an included one, takes place. The discharge is rapidly taken up by small sponges in forceps; the opening into the abscess cavity is gradually enlarged as the leakage diminishes, the cavity finally wiped out with dry gauze sponges, the appendix sought for and adhesions broken up. When the appendix is freed, the usual procedure of ligating the mesoappendix is followed, then the appendix is excised and the stump treated in any of the following ways: The Dawbarn inversion method; clamping with a strong

forceps, on the principle of the angiotribe, near the base, cutting off above the forceps, then inverting the crushed stump; and the usual method, that of ligating the appendix at its base and cauterizing with carbolic acid the exposed and everted mucous membrane. Should the appendix be bound down to other viscera so closely that freeing it would impair the integrity of any of the surrounding organs, I strip it out by splitting the serous and muscular coats at some point where possible, and then shell or strip out the mucous canal, ligating at the usual site. This stripping method is exceptionally easy and can always be used in difficult adhesion cases. Recently I stripped out an appendix seven inches long that was followed to the cecum, which had not descended, but lay in the site usually occupied by the hepatic flexure of the colon.

When free pus of the serous variety is present in the general cavity, I sponge the pelvic cavity as dry as possible and close the wound with or without drain. When gangrene of the appendix and suspicious mesoappendix are present, drainage for from twenty-four hours to the time required as shown by the discharge, or by temperature chart, and pulse, is done.

I do not wash the entire cavity, having given up this method six or eight years ago, nor do I wipe out the circumscribed abscess cavities with peroxide and salt solution, as formerly, but I sponge these abscess cavities dry, and may wash out with a salt solution sponge, and then drain or not, as experience has taught me. The drainage is usually a small cigarette drain, made with rubber tissue, including a piece of sterile gauze loosely rolled. This passes down into the pelvis, or simply into the iliac fossa, as indicated by the extent of the abscess, etc., calling for drain.

The incision is closed to the emergence of the drain, when such is used, by layers, and a provisional suture is placed quite close to the drain, so that, in case the conditions arise that will warrant the removal of the drain in a day or two, this suture can be tied, thereby allowing a primary closure to take place.

After Treatment.—A movement of the bowels is desirable in the first twenty-four hours following the operation, and it is my custom to give from five to ten one-tenth of a grain calomel triturates as soon as the vomiting ceases. When free seropus has been present and the abdominal wound is sewed up, from half an ounce to one ounce of magnesium sulphate and from eight to twelve ounces of water at 100° F. is given by the rectum before the patient is out of the influence of his anesthetic. Nothing is given by mouth in the more serious cases until the bowels have moved or flatus has been expelled per rectum. After the bowels have moved, the patient is allowed milk and broth diet for twenty-four hours; then if the temperature is under 101° F., light diet is given, and regular diet as soon as the chart shows a temperature of 99.5° F. or under. A standing order for cathartics, if necessary to produce a movement daily, is given.

When drainage has been used change the abdominal dressings as often as discharge and odor demand, but do not remove or change the drain until the third to fifth day, and even as late as the seventh day.

The patient is allowed to roll whenever he likes, and is allowed to sit up in bed, if not drained, on the third or fourth day; out of bed on the fourth or fifth day. If drained, he is placed in a semi-sitting position as soon as he is out of ether, and sits up in bed the earliest possible moment that the wound will allow.

60 West Fifty-second Street.

PITYRIASIS ROSEA: WITH A REPORT OF SEVERAL CASES OF THIS DISEASE MISTAKEN FOR CUTANEOUS SYPHILIS.

By FRED WISE, M.D.,

NEW YORK.

CLINICAL ASSISTANT AND ASSISTANT RADIO-THERAPEUTIST, NEW YORK SKIN AND CANCER HOSPITAL.

It is a common occurrence in the public clinics for diseases of the skin, as well as in private practice, to see patients with nonsyphilitic cutaneous lesions, who give fairly reliable histories of having undergone antisyphilitic treatment for the skin diseases with which they are afflicted. Some of these patients may complain of mild, but unpleasant symptoms which accompany the ingestion of mercury in moderate doses; others, however, often present telltale evidences of this treatment—carried up to the point of severe mercurial poisoning—prescribed by the physician, under the impression that he is dealing with a case of syphilis.

Not a few practitioners, many of whom may be acute diagnosticians and skilful therapeutists in other branches of the medical art, will frequently, when confronted with an unfamiliar lesion of the skin, follow the time-honored dictum which has been laid down by their predecessors: "When in doubt, call it syphilis, and treat it as such." It must be admitted that the dermatologist of large experience sometimes resorts to this measure to determine the nature of the disease he is called upon to cure, and to establish the existence—or nonexistence—of active syphilitic disease in his patient. This procedure, however, is gradually falling into disuse, thanks to the development of more exact diagnostic methods, and to the more frequent employment of biopsies as a routine measure, in cases where doubts exist regarding the nature of the disease in question. Very often, patients are seen, in whom only a tentative diagnosis of syphilis can be made, relying upon the so-called "therapeutic test"—a very uncertain weapon—to settle any doubts as to the presence or absence of specific disease. That this unscientific method of diagnosis may be superseded, in the near future, by a simple procedure involving the microscopical search for the spirochete of syphilis, is conceded by the majority of writers on the subject to-day; whether it will be possible to dispose of the doubtful eruptions of *late* syphilis in the same facile manner, time alone will show.

Pityriasis rosea, or pityriasis maculata and circinata, is not one of the common diseases of the skin (according to Crocker, it occurs once in about 250 cases)—but its lesions present one of the many pictures which the unpractised eye is prone to confound with dermatoses of totally different origin and character. When it is considered that diseases of as common occurrence as acne, eczema, psoriasis, and even scabies, are only too frequently submitted to antisyphilitic treatment by the general practitioner, it is small wonder that pityriasis rosea, with its acute onset, wide distribution, and occasional adenitis is consigned to a similar fate in the hands of the well-meaning but hasty diagnostician.

During the past year, I obtained the histories of

several dispensary patients affected with pityriasis rosea, all of whom had been treated for supposed syphilis before coming to the New York Skin and Cancer Hospital. These patients had been assured by their respective doctors that the eruption on their skins was a manifestation of syphilitic disease, and that a long course of treatment was necessary to "purify the blood," and to prevent further serious complications.

Case I.—John F., age thirty-three, single; cabman. General health good, ruddy complexion. The patient shows no evidence of syphilitic disease, but he admits having had a preputial chancre at the age of twenty-two, followed shortly after by an eruption of "spots and pimples" on the chest and abdomen. He states that his physician made the diagnosis of syphilis, and that he took medicines at irregular intervals, during a period of two years. Since the subsidence of the roseola, he has been free of any eruptions on the skin, and apparently has had no symptoms referable to syphilitic disease. During the last two weeks he has been troubled with alternate attacks of diarrhea, followed by constipation, but has felt well in other respects, and has taken no medicines whatever to relieve the intestinal trouble. Ten days ago, after a night of excessive indulgence in beer, he noticed two reddish spots, each about as large as a dime, situated near the right nipple, his attention being directed to the lesions by a slight itching sensation. Eight days later he discovered that his chest, upper arms, and back were, more or less, diffusely covered with an eruption resembling the initial lesions on the chest, and that the itching, though not severe, had become uncomfortable. He now decided to consult his doctor. Suspicion as to the nature of the treatment he had been receiving was at once aroused by the foul breath of the patient. Examination of the mouth revealed a decayed condition of most of his teeth, and a well-marked mercurial stomatitis.

The skin presented an eruption bearing some resemblance to a maculopapular syphilide. The macules ranged in diameter from a pea to a ten-cent piece, were pale-red in color, and partly disappeared under pressure with the finger. Those on the shoulder-blades and below the clavicle were beginning to clear up in the center, leaving a slightly scaly ring at the periphery; two or three of the lesions, viewed with the light striking them at an angle, presented a parallel wrinkling of the center of the discs—an appearance considered to be of diagnostic importance. The papular elements were limited to the axillæ, and the skin covering the shoulder-joints; they ranged in size from a large pin-head to a lentil, were rose-red in color, the majority being tipped with a tiny scale. Infiltration was present, but the characteristic "solidity" of the papules of syphilis was not felt. Adenitis could not be demonstrated. The patient complained of moderate itching, which always increased toward evening. He was given a sedative and antipruritic lotion for the skin, which, together with the internal administration of rhubarb and soda mixture, resulted in a complete disappearance of the eruption within two weeks of his application at the hospital.

Case II.—Elizabeth D., age twenty-seven, married; seamstress. Has had two children, both living and healthy; no miscarriages; menstrual history is normal. She has been troubled, almost since puberty, with frequent attacks of rosacea and acne. Her general health had been good until about a month ago, when she began to complain of obstinate constipation, accompanied by frequent attacks of headache and anorexia. The patient states that with the exception of a few pimples on the back and chest, she was not aware of ever before having had an eruption on her body. She noticed the beginning of the present eruption twenty days ago, while taking a tub-bath. She describes the lesion as a spot about as large as a twenty-five-cent piece, pinkish in color, situated on her breast, a few inches below the right clavicle. At the time of the appearance of the eruption, her two children were being treated for ringworm of the scalp, to which she was making daily applications of the tincture of iodine. Under the impression that she had somehow contracted ringworm from her children, she applied the iodine to this "initial lesion" (the primitive patch of Brocq), resulting in an exfoliation and partial disappearance of the patch; a few days later, fresh patches made their appearance on her neck, chest, and buttocks. She consulted a physician, who made the diagnosis of syphilis, and who advised a course of antisyphilitic treatment, not only for her, but for her indignant husband as well.

On examination, the skin presented a multitude of circular and irregular oval lesions, typical of pityriasis maculata and circinata. The skin of the neck, trunk, and buttocks was involved, while a few pale, scattered blotches were apparent on the thighs and upper arms. The eruption bore some resemblance to the circinate, scaling syphilide; the face, head, and hands, however, were free—an important point in differentiating pityriasis rosea and syphilis. As in Case I, so in this patient, a closer inspection of the patches above the clavicle revealed a wrinkling of the superficial layers of the skin, light-brown in color, surrounding which was a narrow, ill-defined, pale-red zone, slightly raised above the normal skin, and bearing fine scales. Below the clavicle, and near the nipple, were seen a number of pale-red rings—some of them complete, others broken—enclosing fawn-colored patches of skin, most of which were beginning to desquamate in fine scales. On the back, between the shoulder-blades, the individual circinate lesions had given place to a diffuse, pink and yellowish, blotchy appearance, with here and there a large, greasy scale adhering to the skin, assuming a resemblance to seborrhoic eczema. The scattered lesions on the arms, buttocks, and thighs were chiefly of the small, macular variety, none of them exceeding a dime in size, and showing no tendency to spread peripherally, or to clear up in the center. The eruption apparently caused no itching or discomfort throughout its entire course. A slight enlargement of the poststernomastoid glands could be made out by palpation. As a matter of precaution, and in view of the presence of ringworm in the patient's home, a microscopical examination of the scrapings from some of the lesions was made, but no spores or mycelia of the trichophyton were discovered.

Case III.—Fanny S., age twenty-five; single, *puella publica*. General health good. Nothing in the patient's history seems to have any etiological bearing upon the present skin disease. She noticed the eruption about four weeks ago. It appeared simultaneously upon the buttocks and in the axillæ, and, in her own words, consisted of "a few reddish pimples and spots, which itched slightly." A few days later, the patient observed that the rash had spread, from the buttocks upward toward the small

of the back, and from the axillæ up toward the shoulders, the back of the neck, and behind the ears. Subsequently a few spots appeared upon the abdomen, chest, and upper arms; the face, hands, and feet remaining free. Her physician pronounced the case to be syphilis.

The skin now shows the eruption in the process of involution. The lesions on the back, and those on the chest and abdomen have partially faded, leaving on their sites light-yellowish, finely-scaling patches of skin. Upon the buttocks, and on the skinfolds of the axillæ, are a number of papules, flat, pink in color, varying in size from a large pinhead to a split pea. The infiltration is rather more pronounced than is usually the case in those eruptions of pityriasis rosea, in which papular elements obtain. On the back of the neck, behind the ears, and on the arms are a few scattered, indistinct, yellowish spots, surrounded by pale-red rings, enclosing small discs of glistening skin.

There is a trifling enlargement of the glands in the groins. She complained of a slight degree of itching. The serum from three papules was stained with Goldhorn's preparation and examined for the spirochete of syphilis, with a negative result. While palpating the papular lesions upon the buttocks, a half-dozen rounded, marble-sized, infiltrated nodules were plainly felt in various parts of the gluteus muscles: the woman had been receiving intramuscular injections of an insoluble preparation for her supposed syphilitic disease. In this case, the patient's calling, in all probability, prejudiced the doctor in his diagnosis.

Case IV.—(Seen in private practice.) Jos. L., age twenty-nine, single; engineer. General health has always been good. He gives an indefinite history of having had sores on the prepuce four years ago, which probably were either chancroidal or herpetic in character. The patient, who is strong and well-nourished, had been perfectly well until two weeks ago, when he was suddenly attacked by what is known as "the bends" (caisson disease), upon emerging from one of the subaqueous tunnels under course of construction around the city. He recovered from this attack within a few hours, and has felt well since. About three days after his attack, his attention was directed, by one of his fellow-workers, to a few reddish spots on the lower part of the abdomen, near the right groin.

As these spots caused no discomfort, little attention was paid to them at the time. Within a week, the eruption had spread over the entire right side of the abdomen, the upper part of the thigh on the same side, and over the left side of the chest and shoulder. At this stage the itching became marked, especially when his work caused the skin to perspire and become overheated. The patient now consulted his physician, who made the diagnosis of syphilis.

Examination revealed the fact that blue ointment, some of which was evident on the skin, had been employed—whether prescribed for the local or for the constitutional effect, or, perhaps, for both, is a matter of conjecture. About four drachms of the ointment had been rubbed into the skin during the week, and already the patient evidenced symptoms of mercurial poisoning—abdominal pains, fetid breath, and diarrhea. The inunctions had altered the natural appearance of the eruption to some extent, causing a mild inflammation of the lesions themselves, and of the unaffected skin surrounding them; still, the diagnosis of pityriasis rosea was made without difficulty. The lesions consisted mainly of well-defined, slightly raised, rose-red rings, varying in size from the diameter of a lentil to that of a dime, bearing fine scales on a narrow peripheral zone, and enclosing light-yellowish patches of skin in the center. The eruption was limited to two distinct groups—one on the right side of the abdomen, the other on the left side of the chest—a distribution which remained unaltered throughout the course of the disease, and which, in itself, would strongly favor the diagnosis of a non-syphilitic rash. Adenitis was absent, and no disturbance of the general health was apparent, aside from the symptoms due to mercurial poisoning, already mentioned.

Crocker, in the "Twentieth Century Practice," speaking of pityriasis rosea, says: "If it were not for the errors in diagnosis to which it may give rise, it would not be an important disease." The histories of these cases bear evidence to the fact that considerable harm may result from errors made in the diagnosis and treatment of a cutaneous disease, bearing a superficial resemblance to, but having nothing more in common, with syphilitic eruptions. To avoid mistaking, and, what is worse, mistreating—this self-limited and comparatively trifling skin disease for an eruption due to syphilitic infection, certain points in the diagnosis of cutaneous diseases in general, should be borne in mind. The consideration of these points should be based, not upon the patient's indefinite and, frequently, distorted history, but upon the picture which presents itself as the patient stands stripped for examination.

As in other diseases, so also here, the symptoms are subjective and objective. Of the former, itching is the only symptom requiring consideration; of the cases described above, two complained of itching; but that this was not very marked was shown by the fact that in neither did the skin present evidences of scratchmarks—proof that the fingernails were not resorted to for the alleviation of this symptom; and although itching of the affected parts in pityriasis rosea is sometimes severe in degree, the majority of patients do not even mention it. This symptom is of some importance, in a negative sense, in differentiating the eruptions of pityriasis rosea and syphilis; for the absence of itching may prejudice the diagnostician in favor of syphilitic disease, in which itching of the skin is but seldom complained of.

In considering the objective symptoms, accuracy of observation comes into play, and should be directed toward certain diagnostic elements—namely, the distribution, configuration, color, and consistency of the eruption under consideration.

Pityriasis rosea appears most frequently upon the abdomen and chest, the buttocks, and the shoulders. In the more extensive cases, the rash involves the arms, almost to the wrists, and, on the lower limbs, it may extend nearly to the ankles. Very often, the rash appears on the neck, up to the line of the jaw and behind the ears, but it is seldom seen to attack the hands and feet, the face and scalp. Here, the distribution of the lesions becomes an important factor in differential diagnosis; for, in the early syphilitic rashes, it is most common to find that the eruption involves the very regions, which, in pityriasis rosea, remain free; that is, the palms of the hands, soles of the feet, face, and scalp. In some cases, the lesions on the trunk arrange themselves

in lines, parallel to the slant of the ribs, or radiating from the sulcus of the axilla toward the chest and shoulders—a form of grouping not observed in syphilitic eruptions. Cases are seen, in which the eruption is limited to one or two separate groups of lesions, situated on opposite sides, or on the same side of the body, the intervening area of skin remaining perfectly free; and a few cases have been reported, in which the lesions were limited, throughout the course of the disease, to one small area on the trunk, or on one extremity. It may be said, however, that in the majority of cases of pityriasis rosea, in which the eruption has been of two or three weeks' duration, the lesions appear most frequently on the abdomen and chest, the upper arms and back, the buttocks and the thighs.

A well-marked case of pityriasis rosea displays individual lesions of various types. Thus the skin may present a simultaneous eruption of macules, papules, rings, and circular or oval scaly patches, varying in size, color, outline, amount of desquamation, and depth of infiltration. The macular and papular elements are most frequently observed at the advancing border of an active eruption—in the axilla, on the upper arms, the thighs, and sides of the abdomen; the older lesions, consisting of irregular, oval, and circular patches, having complete and incomplete peripheral bands, with here and there two or three rings coalescing to form irregular gyrate lesions, are seen usually on the chest, abdomen, and back. Interspersed among these large and small patches are seen irregularly outlined, brownish-yellow, slightly scaling plaques, gradually fading into the normal skin. Usually on the upper part of the chest and back, closer scrutiny will reveal, within some of the smaller and more recent ringed patches, a peculiar, buff-colored folding or crumpling of the skin into parallel folds—the so-called "cigarette-paper crinkling"—mentioned above as being considered of importance in the diagnosis of pityriasis rosea. As the eruption approaches the stage of resolution, the various lesions become more confluent, gradually less-defined, assuming a light-brown color, and, desquamating in small scales, finally give place to a slightly discolored, but otherwise normal skin.

In color, the lesions vary, as they do in configuration. As the name implies, the usual shade is a rose-red or pink; but cases frequently are seen in which the color cannot be depended upon as an aid to diagnosis; for the papules and macules often assume the darker shade of syphilitic eruptions, whereas the color of the ringed lesions can hardly be said to differ very materially, in the majority of cases, from that of a seborrhoic eczema, or a superficial psoriasis. The buff or fawn-colored appearance in the center of the ringed patches is often an aid to the diagnosis.

Infiltration of the skin in pityriasis rosea is always slight or altogether absent, most of the lesions being on the same level with, or only slightly raised above the niveau; but in several cases of the disease in which the papular elements predominated, I have noted a marked infiltration of the papules, especially when located in or near the axilla. The amount of desquamation also varies; the scales from the arms, thighs, and buttocks are usually fine and branny, while those from the back and chest may be large, thick, discolored, and greasy, like those of seborrhoic eczema.

Mention has already been made, in the description of the efflorescence in Cases I and II, of the initial patch, or group of patches, which appears between one and two weeks before the eruption proper becomes generalized. This lesion, or group, described by Brocq as the "plaque primitive," is usually situated on the enterior aspect of the trunk, the favorite site being the abdomen, although it may occur also on the back or the thigh. In patients who present themselves with a well-developed rash of several weeks' standing, it is wellnigh impossible to pick out this or that blotch on the skin with the idea of naming it the initial plaque; in recent eruptions, however, the patch may sometimes be identified by its larger size, darker color, and more abundant scaling. From observation of dispensary patients, I would say that in the majority of cases of pityriasis rosea, the initial patch of Brocq is more often conspicuous by its absence than by its presence. It is, therefore, of little value as an aid to the diagnosis, and the interest which attaches to it lies chiefly in its relation to the etiology, as yet undetermined, of this dermatosis.

From the foregoing description it will appear that in pityriasis rosea we have an exanthem exhibiting lesions often multiform in character, varying in different eruptions and in different regions of the same eruption, but presenting, in its entirety, a picture to be distinguished and differentiated from the other dermatoses to which it bears a resemblance.

In considering the question of differential diagnosis between this disease and the early syphilides, it would be natural to ask: Can not the diagnosis of syphilis be made and confirmed by the various concomitant symptoms to which syphilitic infections give rise? In the majority of cases the answer to this query would be in the affirmative. But there still remains a large number of patients, who, aside from their cutaneous lesions, present not a single additional symptom, or group of symptoms, that would tend to point the way to the correct diagnosis of their maladies.

The scaly and circinate syphilides, for which the rash of pityriasis rosea is most likely to be mistaken, commonly appear at the end of the first, or beginning of the second, year of syphilis. By this time, the usual concomitant symptoms have disappeared, the chancre itself often healing, without leaving a trace behind.

It is in this class of cases, chiefly, that errors in diagnosis most often occur. It is well to bear in mind, therefore, that the nature of a cutaneous disease should be primarily determined, whenever possible, from the lesions seen on the skin, and on the skin alone; in many instances, such a diagnosis would necessarily be a tentative one, to be subsequently strengthened by any corroborative evidence which may be present (for example, on the mucous membranes), and which may tend to confirm the original impression made upon the mind of the diagnostician. This mode of procedure, if persisted in, will soon enable the practitioner to gain a clearer and more correct conception of the various cutaneous diseases which he may encounter in his practice.

Hemorrhage Following Spinal Anesthesia.—Kopfstein reports a case of severe parenchymatous secondary hemorrhage occurring after an amputation performed under spinal anesthesia, and attributes it to vasomotor paresis.—*Centralblatt f. Chirurgie.*

INSUFFICIENCY OF THE GASTRIC MUSCLE.*

By M. GROSS, M.D.,

NEW YORK.

Although I am fully aware of the fact that the various gastric functions are intimately related to each other, I have made muscular insufficiency a separate subject for discussion. The reason for doing so is not only that this function is to a certain extent actually independent of the other gastric functions, but also because the consideration of this subject affords an opportunity to demonstrate the advanced position attained at the present day in arriving at an early diagnosis of these important affections, for the diagnostic aim consists not so much in the recognition of a well pronounced condition of the tissue, as rather in unraveling the evolutionary process underlying the affections, and in the recognition of the transition stage from mere fatigation to positive disturbance of the tissues.

Axioms.—1. Insufficiency of the stomach, also called atony, is a relatively frequent affection.

2. The difference between atony and ectasy, or mechanical insufficiency, is one of principle and not of degree. Simple atony is a part manifestation of local or general disturbance of nutrition; of disturbances of the circulation; of disturbances which lead to general muscular and nervous debility.

3. Only by reason of mechanical impediments and also of complicating more permanent hypersecretion and its consequences, a simple insufficiency may be changed into a mechanical one.

4. In a simple atony the stomach contents are always evacuated, even though tardily; an ectatic stomach never evacuates its contents except with artificial aid, even though food is withheld for a lengthened time.

5. Insufficiency of the gastric muscle is rarely of a serious nature, and then only if a mechanical impediment is superadded at the pylorus. As a rule this affection is favorable to a spontaneous cure and complete recovery; it readily yields to a removal of the causative factor.

Physiology.—The stomach is really never entirely at rest; even when completely empty gentle movements run along its walls in rather long intervals and irregular, short waves. During this relative standstill the secretory apparatus also seems to display some slight activity, most certainly the mucous glands, which cover the entire lining of the stomach with a thin protective mucous layer in order to protect the mucous membrane from extreme degrees of temperature of ingesta and from slight acid effects.

It is only after food has been introduced into the stomach that the peristaltic movements of the muscle display their vigor, the extent of which is distinctly dependent upon the quantity and quality of the ingested material.

We may look upon the normal mode of gastric movements as in the semblance of a wave, one limb of which is steeply ascending and one slowly descending, followed by a prolonged moment of rest, corresponding to the height of digestion; and of a second, somewhat lower wave movement of an undulating character and a jerking, descending limb. The first part of the movement occurs in the fundus, while the second corresponds to the action of the pyloric part, the ingested food being once more vigorously thrown back, and again and again brought into contact with the walls of the stomach in order better to effect its mechanical distribution and thorough saturation with chyme. The conclusion of this motor mechanism is formed by the opening and closing of the pyloric ring, which is only now effected with some degree of regularity.

Aside from this kind of motion there is another one of a totally different nature. In consequence of the contraction of the powerful longitudinal fibrinous bundle radiating from the cardia toward the pylorus, an approximation takes place of these two ostia which serves to elevate the fundus. By this motion the contents of the stomach are brought up to a level with the pyloric orifice, thus facilitating the removal of the chyme.

As a matter of course, in cases of considerable distention of the stomach and weakening of the muscular wall this lifting factor is absent, exacerbating the pathological condition.

Ability of motion is even shown by the exsected stomach to a certain extent, which is probably due to the action of ganglia diffusely distributed in the stomach wall, while the actually regulating element of the uniform movements is probably principally furnished by the vagosplanchnic plexus by way of reflex action.

Pathology.—If the normal activity of the muscle is interfered with by whatever obstacle there may be, the following eventualities may take place: The muscle overcomes the obstacle (1) completely, (2) imperfectly, or (3) not at all.

One of the factors which may enable the gastric muscle to overcome the impediment completely is the reserve force stored up in it. In referring to reserve force it should be remembered that experience has established the fact that the organs of the body are only in exceptional cases called upon to perform the maximum task of which they are capable.

The normal stomach of a healthy man, which for a lengthened period has done but little work on little food, is capable, if required, of suddenly disposing of a large meal. This latent power of an organ, which may at any time be drawn upon, is called the reserve force, and it is owing to this reserve force that the gastric muscle is enabled to accommodate itself, as we are wont to term it, to increased demands. This is still a physiological process.

On the other hand, an obstacle may be completely overcome by compensation, in which case we have to deal with a balancing of pathological disturbances, deficient capacity being compensated by hypertrophy, which, however, may still be susceptible to subinvolution.

Each regulation of function presupposes a certain degree of integrity of the regulating system and its reintegration by the general process of nutrition. The task of regulation therefore has its limits in all directions, even though it is capable of considerable performances; above all, it is dependent upon the circulation of the blood and body fluids, and on innervation.

If, therefore, the gastric muscle is impeded in its compensatory activity, as, for instance, by repeated demands on the part of accommodation, by local inflammations and their sequelæ in hepatic affections, and by intestinal atony or constitutional affections, there will be no complete balance—no sufficient compensation; the condition termed atony develops, which is at first associated with relaxa-

*Read before the Eastern Medical Society, at its meeting in March, 1907.

tion of the tissue and later followed by a distinct enlargement of the organ, clinically shown by the retardation of the digestive process.

In the extreme cases of pyloric stenosis we have to deal with pronounced eccentric hypertrophy with immutable anatomical changes—the "dog stomach," as the surgeons call it. Total inability to overcome an obstacle is a temporary occurrence, an exceptional condition in consequence of acute indigestion, spastic contractions in the pyloric region, etc.

I stated before that the first sign of insufficient compensation is diminished capacity of the gastric muscle, *i.e.* a retardation in the process of digestion. Here we are confronted with a new difficulty, namely, that of determining the normal period of digestion. It certainly happens frequently enough that the stomach is empty two hours after a test breakfast, or six hours after a test meal, but in almost an equal number of cases it may not be empty, without our being justified in describing such an occurrence as abnormal. The fact is that the process of digestion is subject to slight variations even under normal circumstances, as, for instance, in the case of middle-aged people, workmen, or large eaters, so that it will be necessary to make some slight changes in the above named time limits established by Ageron.

In the initial stages of the so-called atonic condition a *restitutio ad integrum* is of course perfectly possible; also in pronounced anatomical changes a return to approximately normal conditions is possible. A stomach of this kind is constantly somewhat enlarged and the evacuations occur at normal intervals.

Then again there are stomachs resembling a pendulous sac, a distinctly fluctuating cyst, which, remarkable as it may appear, are under normal circumstances still capable of performing their task, although there is always a delay, especially when the demand upon them is increased. To this category belongs the various forms of gastroptosis and the atony associated with hypersecretion.

Diagnosis.—The safest method for recognizing the insufficiency of the gastric muscle consists in drawing out the contents of the stomach a certain time after the ingestion of a test meal. This gives at one glance the undisputable result of the work performed by the stomach. If, according to Mathieu-Rédmond, a quantity of more than 180 to 200 c.c. is found to be present one hour after the test breakfast, it is indicative of a retarded function of the gastric muscle. Elsner establishes a comparative measure between the solid residue and the total quantity, a method by which hypersecretory simulations may be excluded. The normal solid residue does not exceed 100 c.c.

When it is impracticable to draw out the contents, other methods should be employed which will likewise enable us to establish an approximately correct diagnosis.

In suitable cases mere inspection is sufficient to enable us to draw certain diagnostic conclusions; there is, above all, the so-called stiffening of the stomach to which Boas has called attention, due to contractions of the muscle which are more or less visible at the fundus of the stomach and demonstrate the exertion made by the gastric muscle in order to overcome a stenosis which is either commencing at the pylorus, or is already in existence. In cases of pyloric spasm the same manifestations may also be observed, although only temporarily.

The other methods of determining the capacity of the gastric muscle are by means of the splashing sound, by percussion, and examination according to Dehio's method, all of which are easily accessible to the practitioner.

The examination of the stomach is carried out at two different periods: (1) on an empty stomach and (2) after the ingestion of a test meal. The colon having been evacuated, the empty stomach is slightly inflated in order to determine its position and to exclude thereby any possible simulation of an enlarged stomach. Following this procedure percussion should be carried out to determine the size of the organ, as the best results are being achieved after these preliminaries.

The next step is to establish by clapotement (succussion) the presence of a possible noise, to determine the size of the stomach and, above all, the elasticity of the stomach walls. This examination is concluded by the application of Dehio's procedure. One to three glasses of water drunk on an empty stomach determine the area of dullness and, consequently, also the position and size of the stomach, whereas a rapid lowering of the dullness after a further ingestion of water provides a certain indication of the dilatability of the stomach, or rather of its loss of elasticity, although this is not necessarily equivalent with decreased motor power.

An atonic muscle, however, will often render good service as a first indicator of a commencing disturbance in the performance of a muscle. On the other hand, an enlargement of the stomach is indicative of a diminution of the tonus and a reduction of the concentric pressure, because it is just the fundus which has to suffer most, the weight of the stomach contents resting upon it; besides, it is this part of the stomach which possesses the thinnest layer of muscle.

A second examination is made after the ingestion of a test meal. In this case, too, the capacity of the gastric muscle is determined by percussion in the recumbent and erect position, by the production of a splashing sound a certain time after the ingestion of the test meal.

The combination of these double examinations will enable us to arrive at definite results. In regard to the method of examination, the inflation with carbonic acid gas should, as was said above, be only slight, because excessive inflation often causes delusive results.

As to percussion, I often employ the auscultatory method, the stethoscope being placed below the xiphoid process or in the pyloric region. Very gentle percussion being simultaneously carried out, the sounds are conveyed to the ear more perfectly, every slight difference in note being distinctly perceptible. I start from the idea that every fair-sized hollow organ produces a certain timbre.

As to the splashing sound, it may be generally stated that its constant and extensive presence is the outwardly perceptible sign of a diminution of the concentric state of tension, *i.e.* of the counter-pressure exercised by the stomach wall after the ingestion of fluid. It is the time and place of its occurrence which makes the splashing sound an important diagnostic symptom. In gastroptosis the splashing sound is of no diagnostic value.

Preceding, in point of time, the splashing sound, and therefore being the very first indicator of a loss of elasticity, and occurring, as it does, at a time when there can hardly be a question yet of dilatation of the stomach, is a flabby sound, produced

only on an empty stomach, which may be explained by the relaxed walls banging together.

The value of the splashing sound as a diagnostic sign is, however, curtailed by the fact that investigations of Zweig, Calvo, and, more recently, Boas, have demonstrated that the finding of fairly large residual masses a considerable time after the ingestion of a test meal is by no means always indicative of a motor insufficiency of the gastric muscle, but is often attributable to increased secretion of gastric juice, the so-called digestive hypersecretion of gastric juice. But experience has taught that the motility is generally also diminished in these cases.

The prognosis is favorable, if the nature of the affection has been recognized early. But also in the dilating stage a restitution is frequently possible if the underlying causes can be reached. Should this not be the case, it is certainly possible to establish complete compensation and to maintain the muscle in that state. This also refers to benign pyloric stenoses, in which it is possible to maintain a relatively good capacity of the organ for decades.

It is important to recognize the affection when it manifests itself in little children by a tendency to functional dilatation associated with great liability of the function of the organ, which is clinically demonstrable without difficulty. Occasional regurgitations in early childhood should direct our attention to this condition, for there is no doubt that sometimes an affection which had been wrongly diagnosed as nervous has turned out to be purely organic.

Therapy.—A few remarks on this head will be sufficient. Insufficiencies of a light degree undergo, as we have seen, spontaneous cure if they are given the opportunity to do so. But even in advanced cases an alleviation of the manifestations can be attained by enjoining partial or, if necessary, complete rest, by finding out the cause, etc. The same applies to the compensatory disturbances of mechanical dilatation.

Irrigation or douches will be indicated in appropriate cases, and then a few sittings will nearly always suffice to achieve a satisfactory result.

Mechanical, electric, and hydropathic measures will be crowned with success in a number of cases, although often rendered superfluous by a systematic hygienic dietetic régime, where such can be carried through.

But here, as well as in many other sections of pathology, the physician will be obliged to leave a great deal to the slow but unmistakable influence of vis medicatrix naturæ; a more negative treatment —prevention of untoward influences—being likely to lead to better results than exaggerated interference.

315 Second Avenue

Abadie's Symptom in Tabes Dorsalis.—C. Negro describes Abadie's symptom as hyperalgesia of the tendo Achillis when pressure is made on the sides of the tendon at the level of the malleoli. This is present in normal persons, but according to some authors it is absent in those suffering from tabes dorsalis. The author has experimented on ten cases of tabes to see if this sign was always absent. The analgesia was found in three out of the ten patients, while Abadie found it in 80 per cent. of those he observed. It may be found only on one side. There may occur hyperalgesia instead of analgesia to pressure.—*Rivista Neuropathologica.*

VULVOVAGINITIS IN CHILDREN WITH ESPECIAL REFERENCE TO THE GONORRHEAL VARIETY AND ITS COMPLICATIONS.*

By HERMAN B. SHEFFIELD, M.D.,

NEW YORK

INSTRUCTOR IN DISEASES OF CHILDREN AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; VISITING PEDIATRIST TO THE YORKVILLE HOSPITAL, AND THE GERMAN POLIKLINIK.

Notwithstanding recent advances in bacteriology and microscopy, the profession is not as yet in accord as to the exact nature of vulvovaginitis in children. Some physicians still doubt the fact that most cases are due to the gonococcus of Neisser and are highly contagious, but tenaciously cling to the "scrofulous" theory of the disease and recommend tonics to combat it. As a result, innumerable cases run at random, leaving sources of contagion in public schools and baths, homes, and hospitals, with apparently no one in authority to check the further spread of the affection.

The necessity of presenting the subject in question in a clear, concise manner, and repeatedly discussing it so as to arouse the interest of the profession is, therefore, quite obvious.

Accordingly, permit me to offer a classification of the different varieties of vulvovaginitis from the etiological point of view. Thus:

(1) Catarrhal vulvovaginitis, which is generally due to (*a*) lack of cleanliness or (*b*) chemical irritation.

(2) Traumatic vulvovaginitis, which is caused by (*a*) masturbation (?), (*b*) mechanical injury, or (*c*) indecent violence.

(3) Parasitic vulvovaginitis, which is due to (*a*) oxyurides, (*b*) saprophytes, or (*c*) pathogenic bacteria, especially the gonococcus.

The first variety of vulvovaginitis is usually met in poorly nourished children of overcrowded tenement districts, who receive a thorough cleansing on very special occasions only. As a rule, these cases begin with vulvitis, the vagina becoming gradually involved by extension of the inflammation. Catarrhal vulvovaginitis is not always limited to the very poor, and the physician need not hesitate to suspect dirt even under the most elaborate apparel.

This variety of vulvovaginitis is also frequently observed in children whose genitalia are exposed to excessive wetting by irritating, decomposing secretions, and excretions—sweat, diarrheal stools, hyperacid urine—and to undue pressure and friction. In former years, when bicycle riding was a national fad, vulvovaginitis was not rarely met in assiduous bicycle riders, undoubtedly as a result of the aforesaid causes.

The consideration of the second, traumatic, variety of vulvovaginitis does not, strictly speaking, belong to the domain of medicine, except as regards the treatment. We are dealing here with faulty habits and criminal traits which deserve serious attention on the part of teachers, the clergy, and jurists. However, as it is the physician who is usually consulted first, a few points of information will prove useful to him, particularly as a warning not to be too hasty in expressing a positive opinion.

I believe that entirely too much stress is being laid by some authors upon masturbation as an etiological factor of vulvovaginitis. It is much more probable that masturbation is a result rather than a cause of it, the undoubtedly existing irritated state of the erectile tissue inducing that bad habit.

*Read before the Gynecological Section of the Eastern Medical Society.

The presence of foreign bodies in the vagina is not infrequently found to be the cause of vulvovaginitis. While some girls will introduce foreign bodies in the vagina with lascivious intent, the great majority of foreign bodies, *e.g.* safety pins, will find their way in the vaginal canal accidentally, and should always be looked for, particularly in cases of long standing.

Occasionally cases of vulvovaginitis are encountered which are the result of indecent violence. The purulent discharge is either nongonorrheal or gonorrheal, the latter only if the criminal who attempted rape had at the time been suffering from gonorrhea. It is well to remember that not every case of vulvovaginitis reported to be due to rape is really such, and unless the vaginitis is associated with actual penetration of the hymen and concomitant signs of inflammation due to violence, the physician should be very cautious in venturing a positive opinion.

Saprophytic microorganisms are responsible for a great number of cases of vaginitis. To them is attributable the vaginitis not infrequently met after acute exanthematous diseases (with or without desquamation) and in conjunction with diverse forms of cutaneous eruptions. The same cause accounts also for the vaginitis observed in strumous and debilitated children suffering from purulent discharges from the nose, ears, etc. Indeed, the number of cases of saprophytic vulvovaginitis would by far exceed all those arising from all other sources collectively were it not for the antagonistic action of the bacillus of Doederlein which normally inhabits the vagina. This vagina bacillus, which is anaërobic and may be cultivated on ordinary media, produces lactic acid during its growth, a quality to which is due the presence of lactic acid in the healthy vagina. In its presence saprophytes, as well as numerous other bacteria, such as the staphylococcus and streptococcus, are unable to develop, and within a short time perish. Gonococci, however, do not yield as promptly to the destructive effect of the vagina bacillus, hence the frequency with which gonorrheal vulvovaginitis is met, notwithstanding the resistance offered to the entrance of gonococci into the vagina by the stratified squamous epithelium lining it.

As stated before, contamination of the vagina by criminal assault is comparatively very rare. Much more frequently infection takes place by voluntary sexual act or accidentally. Little girls sleeping with their parents, elder brothers, sisters, or nurses suffering from gonorrhea, may contract the disease by coming in contact with soiled bedclothes, cotton pads, or other articles used for cleansing purposes.

Gonorrheal vulvovaginitis runs a more or less virulent course, and in hospitals and asylums, where many children are congregated in comparatively close quarters, and frequently make common use of infected bathtubs, toilets, etc., the disease is very apt to become epidemic as well as endemic. In one epidemic under my care, in an orphan asylum, comprising over one hundred cases, it required many months of very active treatment to eradicate the affection. Arrest of further spread of the gonorrhea was not effected until every patient was isolated and kept in bed for several weeks. A biweekly examination of every female inmate of the institution (including the nurses in charge) for vaginal discharge was continued for several weeks after disappearance of the last case of vaginitis.

Such procedures form the main prophylactic measures against the disease. Of course, the patients must be restricted from the common use of chambers, bedding, bathtubs, etc. In hospitals and asylums, admitting physicians should be particularly careful to exclude all children having purulent vaginal discharge, unless provisions are made for the isolation and treatment of such cases. This point is well worthy of consideration, as it would greatly aid in checking further transportation of the disease. As the majority of cases of vulvovaginitis is observed among school children, a suggestion to the health authorities is, perhaps, in order, viz., to instruct the school inspectors to pay more attention to the detection and isolation of the cases of gonorrhea in children than they do now.

As gonorrhea in adults, that of children presents a marked tendency towards grave complications. Among 148 cases under my care, the following serious complications were observed: Purulent ophthalmia, 7; local peritonitis, 4; proctitis, 3; arthritis, 4; adenitis, 12. Several cases of pyosalpinx, endocarditis, and pleuritis are on record. However, the more familiar I became with the course of the disease, and the best means of checking and eradicating it, the less numerous became the complications and sequelæ in my new cases.

After extensive experimenting I found that gonorrheal ophthalmia can best be prevented by frequent cleansing of the genitalia and hands of the patients, and by the employment of a large, tightly fitting vulvar pad. The latter should be changed for a clean one at least every three hours. The child should wear one-piece night-drawers during the night as well as day. The ophthalmia may sometimes be arrested in its incipiency—I succeeded in two cases—by instillation of silver solutions after Credé's method. In view of the unusually rapid progress of the ophthalmia, unfortunately, it is not often that the physician has the opportunity to resort to the prophylactic measures, and nothing else remains but to treat the disease actively and skilfully, and, if not already involved, to endeavor to save the other eye from the dreadful infection.

Involvement of the uterus and adnexa secondarily to gonorrheal vulvovaginitis in most instances results from injudicious use of douches by forcing the vaginal discharge upwards into the uterus, Fallopian tubes, etc. The treatment should, therefore, not be intrusted to the inexperienced.

I believe that I am entitled to the credit of having been the first to call attention (*American Medico-Surgical Bulletin*, May 30, 1896) to the occurrence of gonorrheal proctitis as a complication of vulvovaginitis. The rarity with which this complication is observed, notwithstanding the constant exposure of the anus to the gonorrheal vaginal discharge, would seem to prove the comparative immunity of the skin and mucous membrane of the anus and rectum to gonorrheal infection. Moreover, as proctitis usually does not develop until late in the course of the vaginitis, *i.e.* until the skin of the anus and the adjacent structures has become abraded and denuded by the continued irritation of the vaginal discharge, or by scratching for the relief of the not infrequently accompanying intense itching.

The diagnosis of gonorrheal proctitis is rendered positive by the presence of the gonococcus in the mucopurulent stools.

Like the former complication, arthritis, the so-called gonorrheal rheumatism, also develops late in the course of vulvovaginitis. In the majority of cases the inflammation is limited to one joint, usually that of the knee, and occasionally ends in suppuration and ankylosis.

Inguinal adenitis is quite a frequent complication. The glandular enlargement may increase up to a well-marked bubo. It sometimes suppurates as a result of an additional infection by pus microbes.

The differential diagnosis between the different varieties of vulvovaginitis can readily be made by bearing in mind the previously mentioned classification. No examination should be considered complete without a very careful microscopical scrutiny of the vaginal discharge. In doubtful cases a culture will settle the diagnosis. Furthermore, it is well to remember that several etiological factors may be operative in the production of the vaginitis in one and the same patient. Hence, the finding of pin worms, for example, in the vagina should not lead us to conclude the absence of gonococci.

The treatment of the different varieties of vulvovaginitis is fully outlined in most modern text-books of pediatrics and gynecology. It is, therefore, superfluous for me to offer suggestions in this direction. All I desire to emphasize is that recurrences of the affection after a period of latency are frequent even under the most careful method of treatment. No case of gonorrheal vulvovaginitis should, therefore, be considered cured, unless three or more thorough microscopical examinations of the vaginal discharge prove the absence of gonococci and pus.

IS AN HERPETIC ORIGIN OF PLEURISY POSSIBLE?

By Woodbridge Hall Birchmore, M.D.,

Brooklyn, New York.

It has been said by more than one pathologist of note that when a certain lesion is a symptom of a condition such lesion may alternate with any other lesion symptomatic of the same condition. The condition which we call "gouty" or "rheumatic" is said to be characterized by a distinct group of skin lesions which are described *en bloc* as "herpetic;" this same condition is said to cause inflammatory processes of the serous membranes, notably is this believed, judging by the contributions to periodicals, in respect to the pericardium and pleura.

It is quite certain that if the familiar "cold sore" is in any proper sense an "herpetic eruption," and officially it is "herpes labialis," then certain alternations can be predicated, no matter what this lesion's cause may be. Also, if like eruptions beginning as insignificant bullæ followed by a tenderness, and even persistent painfulness, out of all proportion to the initial lesion, and by the characteristic cicatricial process, are all to be classed as "herpetic," then we can safely say that some of the eruptions which occur in individuals who complain of "attacks of rheumatism," which to a small degree interfere with the free motion of certain joints, are alternatives to such attacks.

But how about such a case as the following? C. A., aged forty-two years, man, white, weight 182 pounds, height five feet ten inches, chest measure (insp.) 44¾ inches, is in the habit which is so usually called "gouty" or "rheumatic." Has frequent attacks of an illness which has been diagnosticated by various practitioners as "rheumatism," and these attacks impede the usefulness of the ankle and knee on the right leg. Less frequent and less severe have been like attacks of the right elbow, and he remembers that on a number of occasions a pain, very sharply defined in its localization, has interfered with activity. The patient locates this pain upon the right side, and he says that when he has tried to take a long breath this same pain has hurt him "like a knife," but this pain has never lasted more than two or three days, and on no occasion has he been forced "to go to bed and nurse it." As we were rather intimate friends, knowledge of these attacks was not wanting me, and I noted that the "herpetic eruption" referred to would follow the muscle soreness and accompany the pain described as within the chest, and on two occasions I had heard, or believed that I had heard, as distinctly as could be wished for any diagnostic purpose, the "friction sound" of the visceral against the parietal pleura.

The question raised had never been pressing, and yet I was often constrained to wonder what sort of condition existed within the chest, especially since, if fever was present, the body temperature was hardly above normal, and the small difference could be easily accounted for without the diagnosis of "inflammation of the pleura."

But early in February I had an opportunity to see an attack, which gave interest to the question which gives title to this note but did not answer it—satisfactorily. Missing him from our ordinary meeting-places, I asked what had put our plans awry, and learned that he was ill at home and was said to be confined to his bed. In a very short time I was at his bed-side, and fortunately the attending physician called to see his patient while I was still with him, and it was but a few minutes before the question, "Is an herpetic origin for pleurisy possible?" was interesting all three of us. From the outset the attending physician declared that the case was peculiar and its course abnormal—decidedly so for any well-behaved classic pleurisy. The physician had heard the friction sound, but was sure that he had not seen any signs of a superficial lesion. He also bade me note that his patient did not appear to find his chief distress in the stab-like pains, from which he should have suffered, but said that the constant muscular pain, "like a neuralgia," was so much more severe that he hardly perceived the other at all. For this reason his chest to the limits of the painful area, as defined by the patient himself, had been poulticed with a clay compound put on hot. In the course of the conversation, the attending physician said: "Contrary to all my previous experience, a slight irritation of the skin has appeared since the poultice was applied." This interested me as suggesting the previous "herpetic eruption," and I asked to see the same. None objecting, as I rather feared the physician would, I saw the eruption in the accustomed location, and *mutat. mutand.* in the very condition I expected.

It is worthy of note that it was already the sixth day, and the "friction sound" was still to be heard at the proper times and places (immediately under the area of eruption), when the needed precautions were taken, and the "friction sound" was still accompanied by the characteristic pain.

This fact at once suggested to me the question which I had more than once put into words in my note-book, "Is there an eruption upon the pleura identical with this superficial one?" and the mental question was answered, or seemed to be, by the facts in hand. Certainly "the pleurisy" was not at all improving, and the case had been under observation nearly, or quite an entire week, during which time the symptoms usually diagnostic of pleurisy, except the pain and the friction sound, were quite wanting, and the treatment so far as it was special to pleurisy had been quite without result, or at least without expected result. The circumstance most impressing the attending physician was the absence of any perceptible effusion, but it was equally interesting to me to note that the patient was less impressed by the respiratory pain than by the muscle-located "soreness," about which he, as usual,

complained most bitterly. It appeared to be quite in accord with the experience of previous attacks that the fear of pain should be extreme, and that the temperatures should agree in various details with the temperatures noted in previous attacks rather than with those supposedly typical of a pleuritic inflammation.

Not wishing to interfere, and having in mind that professional comity must take precedence of friendship, I left, but that same evening the discussion was renewed by a call made at my room by the attending physician, who after my departure was informed of the many attacks of "neuralgia" located on the right side, and specifically in reference to the attacks of pain accompanied by an eruption located almost, if not quite, in the same area. To my surprise I found my friend the physician very much inclined to regard this attack from my point of view, as being simply one of the frequent and almost periodically appearing bits of evidence that the condition, which was the foundation for one and all these symptom-groups, was a diathesis, rheumatic or gouty, as the evidence might impress the diagnostician. For my own part, I admitted that I was quite willing to believe that gout and rheumatism were but the best-known faces of a nutrition disorder concerning whose true meaning we still lack the most essential facts. The attending physician had sufficient confidence in my good will to ask to see my clinical notes in relation to this case, which I at once, and gladly, put at his disposal. In the course of the next few, two, or three weeks I heard that my friend had been sent to a somewhat more genial climate, and I also received a letter from the attending physician, in part as follows:

"While I cannot say that I am converted to your theory, that the outbreak in our friend's case was due to an eruption on the pleura cognate to the vesicles upon the skin, yet I am obliged to admit that, although I had been treating the case for a whole week, on the theory of another origin, no progress had been made."

In my own mind, the case still is open to argument, for certainly the pleurisy acts in most cases as if it were like the eruption upon the cuticle, in a way self limited. Up to now I have collected eight instances of this seeming alternation of a localized pleurisy with an herpetic eruption upon the corresponding area of the skin. Yet we are as far as ever from a perfectly satisfactory answer, either by logic or demonstration, to the question, "Is an herpetic origin to pleurisy possible?" the question which heads this note.

UTERUS OF THE OPOSSUM.

SOME NOTES ON COMPARATIVE ANATOMY AND EMBRYOLOGY, WITH DEDUCTIONS.

By JOHN P. FURNISS, M.D.

SELMA, ALA.

While serving as assistant surgeon, French's Division Hospital, 1863, I was associated with Surgeon H. D. Schmidt, late curator of the Museum Charity Hospital, New Orleans, La. We made dissections of the opossum, and I have been interested in the subject ever since, but it is only recently that I have acquired some new facts connected with it. These facts I have gathered from observation, literature, and personal communication.

Of the twenty-four living species, the common Virginian opossum (*Didelphys marsupialis*) is the largest, and the only one of the marsupials in the United States of America. There is a difference in the sizes of those of the Middle States, Florida, and Texas. Ordinarily it measures, head and body, twenty-two inches, and tail fifteen inches.

There are no living species on the European Continent, though Buffon states that fossil remains are found there in the lower tertiary formation.

They are closely allied to the Australian *Dasyuridæ*, but are distinguished by the hind foot having an inner toe, which, though nailless, is capable of being opposed to the other digits: by the number of their incisor teeth, of which there are five pairs in the upper, and three in the lower jaw; by their perfectly naked muzzles, and their long, naked, scaly prehensile tails, which enable them to be expert climbers. They have the same (two) marsupial, or pubic bones.

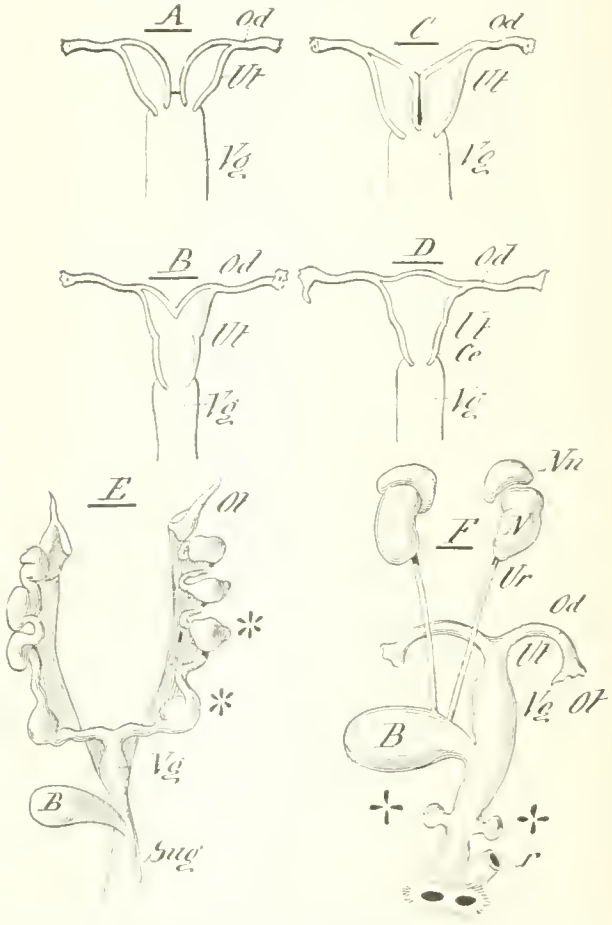

Fig. 1.—Various forms of uteri. A, B, C, D, diagrams showing the different stages in the fusion of the Mullerian ducts. A, uterus duplex; B, uterus bicornis; C, uterus bipartitus; D, uterus simplex; E, female urinogenital apparatus of *Mustelina*, containing embryos (×, ×) in the uterus F, ditto of Hedgehog (*Erinaceus*); *Od*, Fallopian tube; *Ut*, uterus; *Vg*, vagina; *Ce*, cervix uteri; *Or*, abdominal aperture of Fallopian tube; † †, accessory glands; *r*, rectum; *Sug*, urinogenital canal; *N*, kidney; *Ad*, adrenal; *Ur*, ureter; *B*, urinary bladder.

The idea that these bones serve only for attachment of the muscles of the marsupium has been discouraged, as they exist in the male as well as the female.

The animals are nocturnal in their habits, omnivorous, and possess the characteristics of the other marsupials in their low order of intelligence and their great tenacity of life. Their highest exhibition of intelligence is displayed in feigning death in the presence of danger. An entertaining and admirably illustrated account of their appearance, habits, and mode of capture by the Southern negroes is given in Nature Library, Vol. IV. Especial interest is attached to the urinogenital development of these

animals. In the human female fetus the Mullerian ducts are first noticed in the fifth week of embryonal life, and are parallel to the course of the Wolffian ducts. During the second month the ducts unite at a point near their centers; during the third and fourth months they are blended in their lower parts; at the fifth month the cervix uteri can be distinguished. The Mullerian ducts continue to diverge and form the Fallopian tubes. It is at this stage that there is the greatest resemblance to the development found in the adult opossum.

In the marsupials the fusion of the two oviducts is much less marked than in the higher mammals. According to Wiedersheim and Parker, a dilated portion of each oviduct, giving rise to a

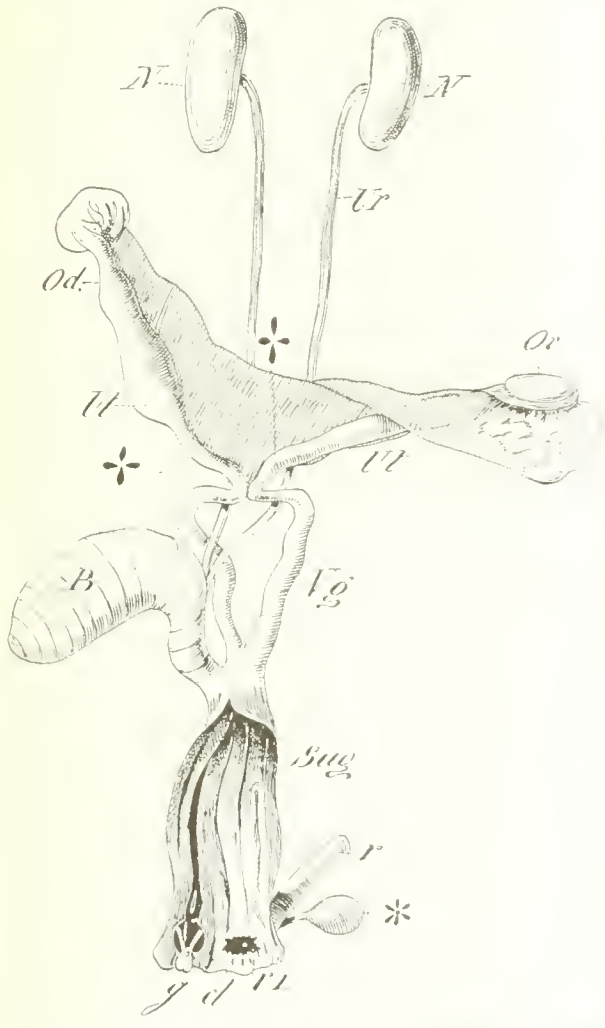

Fig. 2.—Female generative apparatus of *Didelphys virginiana* (after Bourgery and Jacob). *NN*, kidneys; *Ur*, ureters; *Ov*, ovary; *Od*, oviduct; *U*, uterus; †, bend between uterus and vagina; *Vg*; *B*, urinary bladder; *r*, rectum which opens to the exterior *Cl* at *vl*, *g*, clitoris; *, rectal gland.

uterus, is plainly distinguished from the rest, and its narrowed posterior end comes in close contact with its fellow in the middle line. At this point each uterus communicates with the vagina by a distinct os uteri. The vagina curves sharply outward and then backward, opening close to its fellow into the elongated urinogenital canal.

The anus and urinogenital aperture are surrounded by a common sphincter. This fact, or rather ignorance of it, has led many observers to declare that the female opossum had no vulva, and to give expression to many speculations as to how copulation was effected. A clitoris is present in the female of all mammals, and Buffon, quoting Dr. Edward Tyson, an English physician, who claims to have dissected one, states that in the opossum it is double. I am not able to verify this statement, but I do know that the glans penis is bifurcated, the urethra opening in the center. These points of the glans are one-third to one-half inch long. In man, and in most other mammals, the urethra traverses the glans, which is generally rounded, oval, or pointed.

The opossum is a nonplacental mammal. Buffon states that the period of uterogestation is not known. The author of the article on this subject in the Encyclopedia Americana says that it is twenty-six days, and that the young are carried in the pouch five or six weeks. The young are generally born in the spring, and there may be several litters during a season. When expelled from the uteri they are naked, like the young of mice, much more immature, and not larger than an ordinary bean. I have captured them in different stages of development, and at different seasons.

The mother attaches them to the teats, of which there are thirteen in her pouch. In this larval condition the margins of the lips become partially fused to form a suctorial mouth. Strong compressor muscles surround the mammary glands of the mother, and the milk is injected into the throats of the young. They remain attached to the teats until capable of motion and covered with hair.

Hill in classifying malformations of the uterus of the human female gives the following varieties of the aberrant class: (1) The nonfundated and grooved uterus. (2) The septate uterus, which has been more frequently reported than any others, except the bicornate and the double uterus. (3) The bicornate uterus. (4) The double uterus, or uterus didelphys. (5) The uterus with two cervices and one body. (6) Unicornate uterus. (7) Absence of the uterus. (8) The accessory uterus.

He says that uterine malformations are more frequently the result of defectiveness in the right Mullerian duct; that in birds and reptiles the right ovary and oviduct are very rudimentary; that in the monotremes we find a better development of ovary and oviduct on the left side; that from the marsupials through the ascending forms of animal life there are many stages of placental development representing the unerring approach to the perfectly formed structure found in the human race. So, also, are there many uteri representing the gradual fusing of the Mullerian ducts to completeness as is found in the single organ in the woman. Is this paraphrase justified? Wherever a malformation of the human uterus occurs its analogue can be found in the development of some of the lower order of animals.

THE TREATMENT OF STUTTERING.

By E. W. SCRIPTURE, PH.D., M.D.,

NEW YORK.

ASSISTANT NEUROLOGIST, VANDERBILT CLINIC, COLUMBIA UNIVERSITY.

Few departments of medicine have been so neglected as that referring to defects of speech. Perhaps this has been due to the lack of well-developed sciences of mind and speech on which to base the pathology. The following notes give an account of a system of psychological and phonetic principles that may be useful to those who have to care for speech troubles.

The terms "stuttering" and "stammering" are applied in a confused way to a group of speech de-

fects that arise from three causes: (1) Excessive innervation of the speech organs, (2) deficient innervation, and (3) defects of the vocal organs themselves.

The first case may be termed "superenergetic phonation;" there is an excess of nervous discharge to the vocal organs, producing tonic and clonic cramps at various points. This is the condition in what has been called "convulsive stammering" and in ordinary stuttering where a sound is repeated. "Subenergetic phonation" in which the innervation is defective in amount and distribution, produces defective articulation such as is found in alcoholism; this defect may properly be termed "stammering." In the present paper only superenergetic phonation will be considered.

In a case of superenergetic phonation the first problem is to restore control over each group of the vocal organs. Breathing exercises are introduced to reeducate the control of the diaphragm, the abdominal, and the chest muscles. By having the patient place his hands over the abdomen or the chest, he can control his movements by the sense of touch in his hands. When this does not succeed we can apply the fundamental principle of reeducating the muscle-sense by using the sense of sight. A Marey receiving tambour is so arranged that its lever rests on the abdomen or chest; the recording tambour registers the movement on a slow-moving drum which is in front of the patient. Every deviation from an even, steady movement can be seen by him; in this way he controls his breathing movements by his eye. The superenergetic stutterer often cannot control his larynx well: exercises in producing tones are therefore introduced. Defects in articulation are to be cured by showing him how to place his lips and tongue for each sound.

The next step is to teach him to have his organs ready for use when they are wanted. Before he speaks a sentence he must have a supply of air ready by drawing in his breath. At all times he must have ready the first sound of any word he may wish to speak; this I accomplish in the following way:

The typical consonant sounds are first taught. The following list gives the phonetic letters, their names, and some words in which they appear:

[p] pa, as in "*p*ar."
[b] ba, as in "*b*ar."
[f] fa, as in "*f*ar."
[v] va, as in "*v*ary."
[t] ta, as in "*t*ar."
[d] da, as in "*d*arling."
[θ] θa, as in "*th*in."
[ð] ða, as in "*th*ine."
[s] sa, as in "*s*ir."
[z] za, as in "*z*ar."
[š] ša, as in "*sh*ah"
[ž] ža, as in "*j*ardin" (French) or "a*z*ure."
[k] ka, as in "*c*ar."
[g] ga, as in "*g*arden."
[m] ma, as in "*m*ark."
[n] na, as in "*n*o."
[l] la, as in "*l*ark."
[ɹ] ɹa, as in "*r*ah."

This phonetic alphabet is learned by daily practice till it is spoken to perfection and till it becomes almost as familiar as the ordinary alphabet. It is possible to get along without learning the vowels. The patient has also daily written exercises in indicating the sound of the first consonant in each word. Then he is told to write under each word of a selection of verse the phonetic letter for its first consonant. For example, the first two lines of Longfellow's "Psalm of Life" would be treated as follows:

Tell me not in mournful numbers
[t] [m] [n] [n] [m] [n]
Life is but an empty dream.
[l] [z] [b] [n] [m] [d]

Next he is practised in promptly producing any consonant sound at will. Thus, at each tap of a pencil he must promptly say [pa]. He goes through the whole phonetic alphabet in this way until the tap of a pencil automatically releases any sound called for.

This method is sufficient to enable a patient to read perfectly. He simply takes a breath before each sentence or phrase, and begins each word by thinking of its phonetic letter. The whole process finally becomes automatic, and the patient is cured as far as concerns reading.

For conversation we have a more complex condition to which we must apply certain psychological principles. In order to express a thought the person must first have the thought. The stutterer is often in such a condition of embarrassment and mental distraction that he cannot hold a thought long enough to express it. For example, when he intends to say that he needs a motor for his phonograph, he becomes so afraid of being unable to get out the word "motor" that the fear drives the idea out of his mind. He no longer has the picture of the motor with which to set off his speech center; rather, all that he has is the thought of stuttering, which of course sets off the stuttering cramps. Again, he knows that he must begin with the word "the:" he has failed so often that he is anxious about it. He thinks of "the," thereby driving the motor out of his head; but his fear also drives "the" out, and his cramps come on. This flightiness of thought often shows itself in the involved sentences that the stutterer attempts.

To cure this condition, I oblige the patient to describe the objects in the room or in a picture in short sentences. Here is an example: "I am in the doctor's office. A desk is in the middle. The lamp stands on the desk, etc." The description he repeats over and over, not in exactly the same words, but with sufficient sameness to place the exercise half way between the fixed sequence in reading and the entire freedom of conversation.

In this exercise the patient is told first to pick out the thing he is to talk about, *e.g.* "I," "desk," "lamp," etc. If he has any difficulty he can begin by writing a list of them. Then he is to speak the name of the thing; if he has any difficulty he is to think of its first sound. He is not to bother about any articles or adjectives; if he has trouble with "the," he is simply to leave it out.

These exercises are made freer and freer until they pass imperceptibly into conversation. The patient is finally warned that he must always first grasp the thing he wants to talk about, and that he must get its name out, even if he has to omit all articles and adjectives.

20 East Forty-fifth Street.

The Head Zone sometimes aids in distinguishing between acute appendicitis and salpingitis. If the zone commences at the level of the umbilicus, extends to the right lumbar region and to just below Poupart's ligament, it is probably acute appendicitis. If the zone begins a little below the umbilicus with a broad base on the abdomen and extends to a point between the hip-joint and the knee, the case is probably one of acute salpingitis.—*American Journal of Surgery.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, May 11, 1907.

THE APPLICATION OF NEW METHODS OF CLINICAL COPROLOGY TO THE DIAGNOSIS OF DISEASES OF THE INTESTINE.

THE older methods of coprology, including the chemical method of Hoppe-Seyler and the microscopic method of von Jaksch, sought merely to determine the principal constituents of the feces, without regard to the character and quantity of the ingesta and their consequent effect on the digestive organs. The physiological method of the Vienna school abandons minute analysis, and merely determines the proportions of proteids, carbohydrates, fats, and ash as indicative of the mode of nutrition and the power of intestinal absorption. (René Gaultier, *La Science au XXme Siècle*, January 15, 1907).

The new methods, as employed by Dr. Albert Robin, are based upon the examination of the fecal residuum of a test meal, so composed as to call forth the activities of the various intestinal glands, so that, in the case of normal digestion, only traces of the constituents of the meal appear unchanged in the feces, and in other cases the condition of the intestine and its glands may be inferred from the degree to which the various aliments have been assimilated. The dejecta of the test meal are easily differentiated from other feces by the administration of a capsule of carmine powder before and after the meal. The feces, thus differentiated, are examined microscopically, chemically, and, if necessary, bacteriologically, and the time occupied in traversing the intestinal tract is also noted.

This method of examination, in the first place, makes possible a more precise diagnosis of certain disorders designated as duodenal dyspepsias. These dyspepsias are merely symptomatic manifestations of organic or functional disturbances, which, whatever their primary cause may be, have their seat in that part of the tract which, by its production of such substances as secretin and enterokinase, and by its reception of the biliary and pancreatic secretions plays a very important rôle in digestion. The method enables us to detect, almost with certainty, the existence of pancreatic in addition to biliary deficiency, and to distinguish certain affections of the pancreas from suspected or coexistent biliary lithiasis. In a word, this method of studying the functional activity of the intestine completes the clinical diagnosis by giving information of defect, excess, or other abnormality in secretion, absorption, and peristaltic action.

From these data the physician imbued with the principles of functional therapeutics as taught by Robin may deduce a treatment that will modify the perturbed functions, instead of combating imperfectly known causes of disease by theoretical methods. In diseases of the liver, for example, the determination of the degree of activity of that organ, combined with the knowledge of the action of various foods and drugs, will give precise and practical indications for the treatment of disorders of its function. The same remark applies to certain varieties of acid dyspepsia. The authors have also found the new method very useful in the diagnosis and treatment of the varied intestinal troubles of tuberculosis, including the diarrhea of secretion of the incipient stage of that disease, the gastrointestinal atony and catarrhal enteritis, which accompany the second stage of pulmonary tuberculosis, and the colliquative diarrhea and ulcerous enteritis of the final stages.

Finally, the list of the practical applications of this method of functional exploration of the intestine includes digestive troubles, in which no well-marked lesions of the alimentary canal have been discovered, and which apparently are purely functional. In these cases the method becomes a reliable guide in the construction of a rational diet, adapted to the digestive capacity of the patient. Some persons, for example, digest and assimilate fats very well, while others, because of some physiological idiosyncrasy which is not suspected until after the examination of the feces, allow much of the fat ingested to pass through the alimentary canal unchanged. Some persons, again, possess the power of assimilating all the albuminoids ingested, while others lose in their stools two-thirds or even three-fourths of the proteid constituents of their food. These various digestive idiosyncrasies may be detected and differentiated by the regular and systematic analysis of the feces. Thus the physician can compute the quantity of each of the proximate principles required by each of his patients, increase the amount of foods that are well assimilated, and diminish the proportion of those not assimilated, in accordance with the cardinal principle that a man lives, not by what he eats, but by what he digests.

THE TOXIC REACTION FOLLOWING EXPOSURE TO THE X-RAYS.

EVIDENCE has been accumulating within recent years that the deleterious effects of the Roentgen rays are manifested not only on the skin and superficial structures of the body, but also on the internal organs. Of these effects the most marked, and perhaps the most dangerous, is the reaction which in many ways simulates an acute intoxication. This may be of such an extreme type as to produce a fatal ending, and it is therefore a most important matter to determine the character of the trouble in order that suitable means may be devised for overcoming or preventing this complication of a very valuable therapeutic procedure. The subject has recently been studied by Edsall and Pemberton (*American Journal of the Medical Sciences*, March, 1907), who report three cases in which a most severe reaction occurred after one exposure to the rays. Two of these ended fatally, while the third patient became

profoundly ill, but ultimately recovered. Fortunately, the writers had, for another purpose, made some studies of the metabolism in two of these patients, before the application of the *x*-rays, and were thus enabled to determine the alterations at the time of the reaction. In one case the *x*-rays were applied for the treatment of a pernicious anemia, the exposure being brief and of mild intensity. Within a few hours the man became violently ill, there was a chill, the temperature rose to 103.4° F., the pulse became rapid and weak, and general prostration was marked. During the following week there was some improvement, but the change was slight and three weeks later the patient died.

The second patient presented the typical lesions of rheumatoid arthritis, and *x*-ray exposures were ordered for the treatment of his joint conditions. Only one was given, and this involved merely the arm, but as the trunk was not screened it received a more or less diffuse exposure. Here also there followed a condition of prostration which verged on a moribund state, but from which recovery took place within a week. It should be noted that in both of these cases there was evidence of a general toxic condition, as shown by the slight rise of temperature, nausea and vomiting, loss of appetite, and moderate prostration. The chief point in the metabolism of these two patients is the remarkable drop in the excretion which followed the exposure, this drop being followed by an equally striking rise in the excretion to a point much beyond that which it had previously been. This drop was not due to a reduction in the food, for in one instance it occurred before any reduction in the food had taken place, and in the second there was no marked reduction in the intake.

In explanation of this curious phenomenon, the authors venture to suggest a theory based partly on what we already know regarding the action of the *x*-rays in increasing tissue destruction. It is probable that, when the patient suddenly becomes toxic, this is due to the fact that the organism is overwhelmed by the necessity for carrying on the complete disintegration of a mass of products of tissue destruction, and, as the body reacts, the complete disintegration is accomplished and the products are excreted. The fact that the patients were already the subjects of toxemia helps to explain the reason for the occurrence of the condition under circumstances which would not normally have been present. It also offers an explanation of the fact that a toxic reaction occurs only occasionally, and serves as an indication of when to beware of employing the *x*-rays as a remedial measure; for, when a certain degree of general intoxication is already present, the additional demands upon metabolic activity produced by the rays may serve to turn the balance in an unfavorable direction.

VON BERGMANN'S LAST ILLNESS.

It is not unusual to find that the fatal illness of well-known medical men is surrounded with considerable mystery, and the daily press in particular is apt to contain speculations without number as to the probable cause of death in such instances. Thus in the case of the celebrated surgeon von Bergmann it was variously reported in the cable dispatches to the American press that he had died of appendicitis, of peritonitis, and of cancer, and we find that even among the German papers no authentic account appeared regarding a matter which was the subject of so much interest on the part of his colleagues.

This entirely legitimate desire for information has been satisfactorily met by the publication of a report in the *Deutsche medizinische Wochenschrift* (April 11, 1907) by Professor H. Schlange, who attended von Bergmann in his last illness. It seems that the latter had suffered more or less from intestinal disturbances which were traced to an attack of dysentery contracted during the Russo-Turkish war, in which campaign Professor von Bergmann took an active part as a military surgeon. During the succeeding years several attacks occurred which simulated intestinal obstruction but were invariably relieved by local treatment. During the past year the patient gradually lost weight and strength and was troubled a great deal with sciatica. In March last evidences of chronic intestinal obstruction again appeared, and this was not relieved by the usual means. The distention increased, the abdomen became very tender, and it appeared to Professor Schlange, who had been called in consultation, that an incomplete obstruction of the gut had been converted by the presence of a peritonitis into a complete one. On account of the extreme weakness of the patient, it was thought advisable to make an artificial anus under local anesthesia, which was accordingly done in the region of the cecum. The distended cecum was opened within a very few minutes, and after the passage of considerable flatus and some fecal matter, the patient for a time felt greatly relieved. Very soon he grew weak again and within twenty-four hours the distention returned. The pain became intense and von Bergmann begged that relief be given by the formation of another artificial anus on the left side. This was accordingly done, a section of the descending colon being brought out and sutured in the wound. There were many evidences of an extensive peritonitis, and although some relief was secured after the gas was passed, there was no improvement in the objective symptoms. The patient grew gradually weaker, and death followed about twenty hours later without any attendant suffering.

Von Bergmann himself had asked that an autopsy be made, and this showed the presence of very extensive peritonitis. The ascending and transverse colon was so intensely dilated that rupture seemed imminent, and at the site of the splenic flexure was a sharp, angular constriction which was firmly fixed by dense bands of adhesions. The pancreas was considerably hypertrophied, and there were numerous areas of fat necrosis scattered throughout the abdominal cavity. Otherwise no abnormal lesions were found. The complicated nature of the case shows that there was little possibility that a previous operation could have saved the patient's life, and the autopsy findings prove conclusively that there were no evidences of malignant disease present as was stated in some of the earlier reports.

A Suggestion in Regard to the Treatment of Leprosy.

The therapeutic problem of leprosy has so long baffled solution that one is inclined to view with some scepticism the report of a new method of treatment which is considered very promising by its originators. Deycke and Reschad, who in the Gulhane Hospital of Constantinople have abundant opportunities for observing lepers, describe in the *Deutsche medizinische Wochenschrift*, January 17, 1907, the steps by which, after a period of experimentation extending over more than two years, they have been enabled to produce a therapeutic agent by means of which they believe that a great deal may be done towards the cure of the disease. This substance, a crystallizable fatty body, to which, on account of its firm consistency, the name "nastin" is given (*ναστός*, close-pressed), is derived by a process of ether extraction from cultures of a variety of streptothrix obtained from a case of leprosy. The fatty substance in question appears, like the fatty component of the tubercle bacillus, to render the organism more resistant to the bacteriolytic powers of the body fluids. On injecting it subcutaneously into normal individuals no reaction is produced, but in lepers bacteriolysis seems to be markedly favored. This is explained by the assumption that the nastin causes an active immunity whereby the body fluids acquire an increase in antibodies hostile to the specific organism of leprosy. This reaction is possible in leprosy because owing to the extremely chronic nature of the malady the general powers of resistance are not impaired to any great extent during the earlier stages of the disease. The authors do not claim that the nastin injections are of value in the severest or even in the ordinary advanced cases, but they are convinced that by this means it is possible to arrest the disease process in slight or moderately severe cases and in some instances to effect an actual cure. So far their results have been obtained from the unaided use of the new remedy, but now, having satisfied themselves of its value, they are about to combine its administration with the usual therapeutic measures, in the hope that in this way still better results may be secured.

Solar Baths in Tuberculous Peritonitis.

Considerable divergence of opinion still exists with regard to the treatment of tuberculous peritonitis. Many contend that the serous form particularly is susceptible of spontaneous cure, while others energetically claim that laparotomy is the only salvation. Among those who have had an opportunity to follow up the results in a large number of cases in which laparotomy had been done, the favorable opinion previously held has been considerably modified and internal treatment is credited with a greater proportion of recoveries than the purely surgical procedures. The reason for the favorable effects after a laparotomy has not as yet been determined, although there may be some truth in the assumption that "letting the daylight in" has brought about the curative reaction. In the belief that sunlight was actually the important factor, Oppenheimer (*Zeitschrift für physikalische und diätetische Therapie*, January, 1907) was led to try solar baths in patients the subject of tuberculous peritonitis. He employed the procedure in two cases with good success, the children gaining in weight as the ascites disappeared. The rays of the sun were allowed to shine for definite periods daily directly on the abdomen while the children were out in the open air. Oppenheimer thinks that the therapeutic effect of these sun-baths is due entirely to the local hyperemia of the peritoneum which is produced by the sun's rays, and that in this respect their action is analogous to the condition brought about by the performance of a laparotomy, for Nassauer among others has observed that this is what actually takes place. The results obtained in Oppenheimer's cases are by no means conclusive, but they suggest possibilities which may be employed before any more radical measures are resorted to. We have begun to realize that fresh air and sunlight are among the most important curative factors in the treatment of tuberculosis, no matter what its location in the body, and Oppenheimer's observations lend support to this view.

Some Dangers of the Rubber Nipple.

Apart from the fact that mothers' milk is the best food for nursing infants, artificial feeding is attended with dangers peculiarly its own. Cow's milk is, for various reasons, more liable to contamination and deterioration than mothers' milk. Moreover, the common method of feeding through a nipple, and also the use of the device known as a comforter or pacifier, may be responsible for deformities of the jaws and other secondary disorders. The subject is considered at some length in a communication by Dr. T. F. Pedley in the *British Medical Journal* for October 20, 1906, on the basis of experience in India, but his facts and conclusions are equally applicable to other localities. As he points out, the infant at its mother's breast takes the nipple far into its mouth and exerts compression by means of the lips and of the tongue against the palate, thus effecting expulsion of the milk. The jaws take little or no part in the act. On the other hand the rubber nipple of the ordinary nursing bottle, and more especially of the comforter or pacifier, is held firmly between the lips and is pressed by the encircling tongue against the middle of the hard palate, while the cheeks are drawn inward. Owing to the small orifices often present in the rubber nipple, the milk, instead of flowing in, must be sucked in, and with it enters a certain amount of air. As a result of the conditions described, deformities of varying degree occur in the superior maxillary bone, whose transverse diameter becomes diminished, with elevation of the palatal arch and projection forward of the alveolar process. In conjunction with these changes the nasal fossæ become narrowed, the septum buckled, the deflected vomer approximated to the displaced turbinated bones on one side, or any or all of these delicate bones to each other, with resulting obstruction to or abolition of nasal respiration. Mouth breathing is thus favored, with all its unpleasant consequences. Sometimes the arch of the lower jaw is narrowed from contraction of the symphysis during the process of bony union. In addition there is the danger of infection from the introduction of bacteria with the rubber devices under consideration. The evil results described are naturally the greater the earlier in life the use of the rubber nipple is begun and the longer it is continued, and they are more pronounced from the employment of the pacifier than from that of the nipple. For the use of the pacifier there is no legitimate excuse, and as a substitute for the nipple Pedley recommends a good-sized rub-

ber finger stall attached to the spout of a vessel like a feeding cup or an ordinary feeding bottle. Older children can be taught to drink from a cup.

The Pungency of Tobacco Smoke.

A recent *Lancet* article calls attention to the fact that probably not more than one-seventh of the nicotine survives in the smoke. On the other hand some observers have failed to find any nicotine at all in the smoke, and have considered pyridin as the harmful constituent. This body forms a large element in the oil which collects in the tobacco pipe, and this oil is very poisonous. It would appear, therefore, that the toxicity of tobacco may not have any relation at all to its nicotine content, and it is well known that some tobaccos contain a very small proportion of nicotine yet yield a smoke which is decidedly toxic. Certain Turkish tobaccos, for example, are almost free from nicotine, while they produce a pungent toxic smoke. It would be pretty safe to assert that all smoke is more or less toxic. If wooden shavings were substituted for tobacco in the pipe there can be little doubt that the smoke would have evil effects, but there is no nicotine in wood. The fact is, that the toxicity and pungency (though the terms are not necessarily interchangeable) of tobacco smoke are dependent chiefly upon the nature of the products of destructive distillation of the plant fiber. The pungency of tobacco smoke seems, at any rate, to bear some relation to the proportion of organic acids present in the leaf. The amount of these acids, amongst which citric and malic acid are chief, varies widely, and as a rule that tobacco gives the softest and least irritating smoke which contains the smallest amount of organic acid. The citrates and malates on destructive distillation give acid products. Of two cigarettes the tobacco of which contains approximately the same amount of nicotine, one may be found to give an unirritating and the other an acrid smoke. When the two tobaccos so concerned are further examined it may be found that one generally yields a larger ash than the other, corresponding with a larger proportion of organic acid. The tobacco with a larger proportion of organic acid is more liable to give an irritating smoke. In spite, however, of all the learned, and oftentimes unlearned, ratiocination that has been devoted to the subject of tobacco smoking, it appears that we still have not progressed much further than the empirical observation that the injuriousness or harmlessness of the weed depends not so much on its character or on the way it is used, as on the kind of man who does the smoking.

Acute Pulmonary Edema.

Edema of the lungs is most commonly met with in states of lost compensation during valvular or muscular heart disease, in conditions of cachexia, in grave infectious diseases, or in the terminal phases of acute or chronic nephritis. In addition to this form there is another which is independent of the above factors, but which from the suddenness of its onset, the alarming character of its symptoms, and the mortal peril in which it places the patient, closely resembles angina pectoris, and should therefore demand an equal degree of attention. Riesman, writing in the *American Journal of the Medical Sciences* for January, 1907, calls attention to the fact that, although this condition has been recognized for a long time, it receives very little or no mention in our textbooks. The condition, as shown by the cases hitherto reported, including six by the writer, comes on without apparent cause, and often kills within a short time. It is associated with a variety of affections which in the clinical sense may be considered in the light of causes, among which are arteriosclerosis, nephritis, angina pectoris, myocarditis, valvular lesions, asthma, the acute infectious diseases, pregnancy, angioneurotic edema, and certain other obscure conditions such as hysteria. Recovery from an attack is frequent, but there is a striking tendency to recurrences. The pathogenesis is obscure; Riesman considers that vasomotor disturbances and a disproportionate activity of the two ventricles, in which the right predominates, are the two chief factors. The leading symptoms of this state are agonizing dyspnea, cyanosis, cough, expectoration of frothy, albuminous fluid, and profound prostration. The characteristic moist râles of pulmonary edema are always heard, more over the upper portions than over the lower. Treatment to be effective, must be prompt. The most valuable remedies have been found to be venesection, dry cupping, and cardiac stimulants. As Riesman truly states, this condition is of sufficient importance to warrant its being accorded a special chapter in medical textbooks commensurate with that given to angina pectoris.

News of the Week.

Council on Medical Education of the American Medical Association.—The third annual educational conference of this Council was held at the Auditorium Hotel, Chicago, April 29. There were present eighty-four delegates, representing twenty-two State Examining Boards, eighteen State Medical Societies, the three departments of the Government services, three college associations, and seven colleges of liberal arts, in addition to the members of the Council. The work of the past year was pointed out in reports by the chairman and secretary. Accounts of the inspection of medical schools were given, as well as the classification of schools based on the State Board examinations during 1904 and 1905, inclusive. Forty-four colleges have adopted the requirements for admission to medical study of at least one year in a college of arts to be devoted to physics, chemistry, biology and one language, to become effective January 1, 1910. Eighteen of these will require two years or more of university work, or plan to give the combined course for the degrees of B.S. and M.D. Several committees reported. Dr. Arthur Dean Bevan was chairman of the conference.

Confederation of State Medical Examining and Reciprocating Boards.—This body met at the Auditorium Hotel, Chicago, April 30. At the meeting a definite step was taken towards the elimination of undesirable medical colleges which issue diplomas to incompetent and ignorant medical students. A committee was appointed by the Confederation to investigate that class of medical colleges throughout the country and report as to their qualifications to carry out the work for which they were established. Accordingly President Spurgeon appointed the following committee: Drs. W. A. Spurgeon, Indiana; B. D. Harison, Michigan; B. F. Bailey, Nebraska; J. B. Stephens, Wisconsin, and A. H. Hamel, Missouri.

Pennsylvania Antivivisection Bill Killed.—An act intended to prevent vivisection and animal experimentation of any kind, either for demonstration in physiology, for scientific research, or for any purpose whatever, which had been quietly introduced into the Pennsylvania Legislature, and had already passed the second reading, was summarily withdrawn from the calendar on the personal appeal of a group of distinguished medical men headed by Dr. S. Weir Mitchell of Philadelphia. Dr. Mitchell pointed out, among other things, that by the provisions of the proposed act it would be impossible to prepare in the State virus for vaccination and also diphtheria antitoxin, as well as to perform various operations on animals common in the farming industry.

New Dispensary for the Philadelphia Polyclinic.—Plans have been completed and estimates have been invited for the erection of a two-story brick and granite dispensary building as an addition to the present accommodations of the Polyclinic Hospital. The new building will be about 80 by 80 feet in size and will contain seven bedrooms, a students' lunch room, kitchen, pantry, four wards, a room for delirious patients, a laboratory, two nurses' rooms, a matron's room, rooms for the treatment of diseases of the skin, nervous system, eye, ear, throat, and nose, lecture rooms, rooms for orthopedic demonstrations, for resident physicians' offices, a students' room, a record room, a pharmacy, a room for massage, two operating rooms, an etherizing room, a sterilizing room, and a large solarium.

Medical Unification Bill.—On May 1 the Senate at Albany passed the so-called medical unification bill by a vote of 40 to 7. This substitutes one board for the present three Medical Examining Boards, and also gives greater recognition to the osteopaths.

Women's Labor Bill.— The Senate at Albany has passed the Hooper bill, which provides that women or minors shall not be employed before 7 A.M or after 10 P.M., nor for more than ten hours in any one day, except on Saturday, or except for the purpose of making a shorter workday of some one day in the week.

Railway Accident Mortality.—The bulletin recently issued by the Interstate Commerce Commission for the three months ended December 31 last shows that during that quarter the total number of casualties to railroad passengers and to railway employees while on duty was 20,944, an increase of 1,094 over those reported during the preceding three months. The number of passengers and employees killed in train accidents was 474, an increase of 207 over the number reported in the last quarter. The number of passengers killed, 180, is the largest on record, except that for the quarter ended September 30, 1904.

Trachoma Among School Children.—According to the Health Department figures, trachoma is rapidly decreasing among school children in this city. There are only 8,700 cases in New York schools now, as compared with the 15,000 of a few years ago. Further accommodation for the operative treatment of the disease is advocated and the subject will be discussed at the next meeting of the board.

Dr. Bryant Honored.—At the regular quarterly meeting of the faculty of the New York University and Bellevue Hospital Medical College, Chancellor MacCracken announced that the university corporation had conferred the degree of Doctor of Laws upon Dr. Joseph D. Bryant, Professor of Anatomy and then of Surgery for the past twenty-nine years, and President of the American Medical Association. The degree was conferred by the Rev. Dr. George Alexander, chairman of the university corporation.

New York Academy of Medicine.—At the stated meeting of the Academy, held May 2, the report of the work of the surgical research laboratory of Columbia University, 1906-1907, was made. There were presentations of specimens, instruments, and papers, with lantern slide demonstrations.

Osteopathic Bill Vetoed by the Governor of Pennsylvania.—Bill No. 211, passed by the Legislature of the State of Pennsylvania, has been vetoed by Governor Stuart. The bill, known also as the Wickersham bill, provided for the establishment of a fourth Board of Medical Examiners in addition to the three already in existence, and the granting of representation to osteopaths on the Medical Council. It is pointed out by the Governor that only physicians of ten years' graduation or more are eligible for membership on the Medical Examining Boards, while the new bill contemplated the appointment of osteopaths of four years' standing or more. It was further provided that any regularly graduated osteopath who had been in practice in the State at the time of the passage of the act should be entitled to license without examination, and also that regularly graduated practitioners of ten years' standing or more in other States should, upon the recommendation of the State Board of Medical Examiners, be entitled to a license without examination, while not regularly graduated osteopaths engaged in practice for two years should be eligible to examination.

Cocaine Bill.—The attempt to change by an amendment the original Smith anticocaine bill, now before the State Senate, was voted down last week. The Senate codes committee introduced an amendment whereby the selling of the drug without a physician's prescription would have been made a misdemeanor instead of a felony, as in the original bill passed in the Assembly. By a vote of 42 to 2 the bill was restored to its former form.

Workingmen's Health Insurance in Holland.—A measure providing for obligatory workingmen's insurance resembling the system now in use in Germany is under consideration by the States-General of Holland. The principal provisions of the law are: Every laborer regularly employed, including domestic servants, who has reached the age of sixteen years, is obliged to insure himself and family against the risk of illness. Those whose annual income is higher than 1,200 florins ($480) are not required to insure. The insurance can take place either in a district bank, instituted by the Government and subsidized by the State, or in any private or corporate insurance company, provided such institution shall give a sufficient guaranty to the Government of its ability to fulfill their obligations to the district bank. The premium is paid by the employer, who deducts the amount from the worker's wages. The whole country is divided into insurance districts, so that each community or aggregation of more than 5,000 people has its own district insurance bank. The indemnity in case of illness consists of free medicine, medical attendance and a sick benefit if the illness lasts more than two days and causes inability to work. If the disability is complete 70 per cent. of the wages is paid out; if only partial 35

per cent. is paid. The compensation is paid during 180 days at the utmost.

To Inspect Cuban Hospitals.—Surgeon-General O'Reilly, after a tour of inspection in Porto Rico, has gone to Cuba to inspect the hospitals of that island.

Queen's Medical Laboratories.—The cornerstone of the new medical laboratories building at Queen's, Kingston, Ont., for which the Ontario Government voted $50,000, was laid on Wednesday, April 24, by Lieutenant-Governor Clark of Toronto, immediately following the convocation proceedings. The building is now well under way. Besides being used for biological purposes, the pathological, bacteriological, and public health laboratories will be in it.

For New Italian Hospital.—The Supreme Court has signed an order permitting the Italian Benevolent Institute to mortgage its property at 165, 167, and 169 Houston street, in order to raise funds for the building of a new hospital. The Italian Government has contributed $60,000 for the endowment of the proposed hospital. The real estate at present held is estimated to be worth $62,000, and the personal property $76,000. The indebtedness of the society is now $15,000. The proposed mortgage is for $57,000, and bears no interest.

Jefferson Medical College (Philadelphia).—In connection with the dedication of the new hospital the members of the faculty of this institution have arranged for a series of clinics, ward walks, and demonstrations for visiting physicians, to be held on June 8, 10, 11, and 12. The committee of arrangements has the following members: Dr. H. Augustus Wilson (chairman), Dr. Henry W. Stelwagon, Dr. Edwin E. Graham, Dr. J. Chalmers Da Costa.

Additions to the Michael Reese Hospital Staff.—The following additions have been made to the staff of this institution: Attending surgeons, Drs. L. A. Greensfelder, D. N. Eisendrath, and E. Friend; attending physicians, Drs. M. F. Rubel, and T. B. Sachs; attending gynecologists and obstetricians, Drs. L. Simon and A. W. Schramm; dermatologists, Drs. E. A. Fischkin and D. Lieberthal; attending pathologist, Dr. Maximilian Herzog; attending The Senate codes committee introduced an amending genitourinary surgeon, Dr. Louis E. Schmidt; orthopedic surgery, Dr. C. M. Jacobs; children's diseases, Dr. J. H. Hess.

Appointment of Dr. Wilder.—Dr. Wm. H. Wilder has been appointed Professor of Ophthalmology in the medical department of the University of Chicago (Rush Medical College), a position vacated by Dr. F. C. Hotz.

Professor E. v. Behring, who some months ago was compelled to give up all work owing to severe neurasthenia, is reported as being completely restored to health and about to return to Germany from Italy, where he has been spending the winter.

Meningitis at Newport.—Another death from cerebrospinal meningitis has occurred at the Newport Naval Training Station. The patient was an apprentice seaman who enlisted four weeks ago, and the other men of the same draft are being held in the detention building, though no other cases have developed.

The Clinical Society of the Jewish Hospital.—This society held its first meeting at the Jewish Hospital, Classon and St. Mark's avenues, Brooklyn, on Friday, May 10. Its membership will consist of the house, visiting, and dispensary staffs of the hospital. The object of the society is to further the interests of medical science, with the aid of the large and varied clinical material at the disposal of its members.

International Congress on Tuberculosis.—Plans on a large scale have already been formulated for the International Congress on Tuberculosis to be held in Washington, D. C., during the last ten days of September and the first ten days of October, 1908. In addition to the scientific conventions it is expected to have a very extensive and complete tuberculosis exhibition, with exhibits from a great number of different countries. The attendance of foreign delegates is likely to be a large one, and thirty public lectures by visiting scientists have been arranged for. The congress is to be held under the auspices of the National Association for the Study and Prevention of Tuberculosis, and the committee engaged in the work of organization at present includes Dr. Lawrence Flick of Philadelphia, Dr. Vincent Y. Bowditch of Boston, Dr. Alfred Meyer of New York, Dr. J. J. Walsh of Philadelphia, Dr. Lawrence Litchfield of Pittsburg, and Dr. Charles J. Hatfield of Philadelphia. The committee has appointed a Secretary-General, Dr. John S. Fulton, of Baltimore, who has opened an office in the Colorado Building, in Washington, and will devote all his time to the organization of the Congress. The sum of $100,000 has already been pledged to defray expenses.

International Medical Association for the Prevention of War.—A meeting will be held in the Hotel Holmhurst, Atlantic City, on June 5 at 8 P.M. to organize formally the American Section of the International Medical Association for the Prevention of War. All physicians interested are invited to be present. The president of the American Section is Dr. Wm. Benham Snow of this city and the secretary is Dr. George Brown of Atlanta, Ga.

New York Entomological Society.—At the meeting of this society, held at the American Museum of Natural History on May 11, the subject of the transmission of disease through the mediation of insects was discussed by Mr. C. Schaeffer.

Berkshire County (Mass.) Medical Society.—At the meeting of this society, held in Pittsfield on April 25, officers were elected as follows: *President*, Dr. George L. Rice of North Adams; *Vice-President*, Dr. J. J. Hassett of Lee; *Secretary*, Dr. I. S. F. Dodd of Pittsfield; *Treasurer*, Dr. W. L. Paddock of Pittsfield.

Southeastern Michigan Homeopathic Society.—Officers as follows were elected at the meeting of this society, held in Detroit on April 26: *President*, Dr. E. J. Kendall; *First Vice-President*, Dr. Hale of Memphis, Mich.; *Second Vice-President*, Dr. E. L. Orneman; *Secretary*, Dr. F. E. Thompson; *Treasurer*, Dr. James I. Murray.

Windham County (Conn.) Medical Society.—At the one hundred and fourteenth annual meeting of this organization, held in Norwich on April 25, officers as follows were elected: *President*, Dr. C. J. Le Claire of Danielson; *Vice-President*, Dr. R. O. Paine of Thompson; *Secretary* and *Treasurer*, Dr. James L. Gardiner of Central Village.

Calcasieu (La.) Medical Society.—At the meeting of this society held on April 26 officers were elected as follows: *President*, Dr. V. A. Miller of Lake Arthur; *Vice-President*, Dr. T. H. Watkins; *Secretary* and *Treasurer*, Dr. George Kreeger.

Dr. Paul Poirier, Professor of Anatomy in the University of Paris, died last week.

Obituary Notes.—Dr. William H. Hotchkiss of New Haven died on May 2 at the age of sixty years. He was graduated from the Yale Medical School in 1860 and had at one time practised in St. Louis.

Dr. Charles Laight, son of the late Wm. E. Laight, died in Rome, Italy, March 31, 1907. He was graduated from the College of Physicians and Surgeons of this city in 1868, served as interne on the surgical division of the New York Hospital 1868-70, and later was connected with the New York Eye and Ear Infirmary until 1880. For many years he resided in Rome, Italy, coming to this country each summer to spend the season at his place in Keene Valley, in the Adirondacks. Interment took place at Rome.

Dr. George H. Fossard of Brooklyn died on May 3 at the age of sixty-eight years. Dr. Fossard was born in Albany and was graduated from the Albany Medical College. After serving through the Civil War as surgeon he practised medicine in Middletown, Port Jervis, and this city. He had not practised for many years.

Dr. Wilson C. N. Randolph of Charlottesville, Va., a great-grandson of Thomas Jefferson, died on April 26 at the age of seventy-three years. He was graduated from the medical department of the University of Virginia in 1855 and for sixteen years was a member of the Board of Visitors of the University.

Dr. J. B. Charlton of Clear Lake, Ia., died on April 27 after a long illness. He was born in 1845 in Pennsylvania, but in 1856 his family settled in Keokuk. He served in the Eighteenth Iowa Infantry through the Civil War, and in 1872 received his medical degree from the Iowa State University. He immediately began practice in Clear Lake, where he had resided ever since. He was four times mayor of the city.

Dr. John Wilson of Liberty, Mo., coroner of Clay County, was killed in a runaway accident on April 19, at the age of thirty-six years. He received his medical education in Kansas City and had practised in Liberty for the past eleven years.

Dr. C. B. Currier of San Francisco died on April 18. He was a native of New England and practised for a time in Vermont. In 1875 he moved to New York city and four years later went to San Francisco, where he had practised ever since. He was one of the founders and the first dean of the Homeopathic Medical College of San Francisco, and in 1906 was president of the California State Homeopathic Medical Society. He was also a trustee of the San Francisco Society for the Prevention of Cruelty to Animals.

Dr. Herbert K. Stiles of Somerville, Mass., died of pneumonia on April 27, at the age of thirty-eight years. He was a graduate of Amherst and received his medical degree from the Harvard Medical School in 1895. He had practised for a time in Roslindale, removing to Somerville seven years ago.

Dr. B. F. Tomlin of St. Louis died on April 26, after an illness of ten days. He was born in Pendleton, Ky., in 1834 and was graduated from William Jewel College, Liberty, Mo., in 1857. He was graduated from the Cincinnati Medical College in 1865.

Dr. Felix Ferriére of St. Louis died on April 20 at the age of eighty-six years. He was born in Bordeaux, France, and came to this country in 1847. After practising for a time in New Orleans he removed to St. Louis in 1885.

Dr. Henry R. Hayden of Los Angeles died on April 20 at the age of sixty-two years. He was born in Winchester, Ia., and after serving in the Civil War was graduated from Keokuk Medical College in about 1867. He practised for a time in Camden and Crete, Neb., and five years ago removed to Los Angeles.

Dr. Ray P. Robbins of Portland, Ore., died on April 10 of cerebrospinal meningitis. He was a native of Minnesota, and had practised in Portland for about three years.

Dr. Frank P. Webster of Norfolk, Va., died suddenly on April 20. He was born in Portsmouth, but had resided in Norfolk for many years.

Correspondence.

VENEREAL DISEASE IN THE CONTINENTAL ARMY.

To the Editor of the Medical Record:

Sir:—As the years roll on the character of the Revolutionary soldiers becomes heroic in our minds, largely because of iteration of their real achievements and partly from a general consciousness of the great importance to us and all mankind that their struggle for liberty involved.

But, although it comes with something of a shock, sober history reveals them as pretty much like other soldiers away from home. The Continental Congress found it necessary to make venereal disease expensive to the soldiers of freedom. On January 6, 1778, Congress voted:

"That the sum of ten dollars shall be paid by every officer, and the sum of four dollars by every soldier, who shall enter or be sent to any hospital to be cured of the venereal disease; which sums shall be deducted out of their pay, and an account thereof shall be transmitted by the physician or surgeon who shall have attended them, to the regimental paymaster for that purpose; the money so arising to be paid to the director-general, or his order, to be appropriated to the purchasing of blankets and shirts for the use of sick soldiers in the hospital."

Thus, it appears, that the followers of Mars who dallied with Venus were mulcted for the benefit of the patriots whose forms of illness had more claim upon the gratitude of a struggling republic. The humanness of the conditions which led to the vote may shatter an ideal or two, but the fact brings the American Revolutionary soldier much nearer to us in actual life than he ever appeared before.

John G. Coyle, M.D.

126 East Thirty-first Street.

OUR LONDON LETTER.

From Our Special Correspondent.

AMEBIC HEPATITIS AND DYSENTERY—INDIAN FEVERS—HYSTERECTOMY—PUBIOTOMY—DR. RENTOUL ON WOMAN'S HEALTH—COLLEGE OF SURGEONS' PRIZES—PROPOSED BIRMINGHAM SANATORIUM—OBITUARY.

London, April 19, 1907.

In a paper on amebic hepatitis at the Medico-Chirurgical, Prof. Leonard Rogers related fifteen cases of fever, in nearly all of which acute hepatitis was present with a peculiar form of leucocytosis. He regarded this as the early stage of amebic dysentery which usually went on to suppuration, constituting amebic abscess of the liver. Large doses of ipecacuanha were given in most cases, even in the absence of any symptoms of dysentery, with a view of arresting latent disease of the larger bowel. The result was a rapid cure of the hepatitis and of the dysentery when present, with cessation of the fever. In some cases there were no symptoms of hepatitis, the cause of the fever remaining unknown until a blood examination showed the leucocytosis. Then the ipecacuanha was given and the fever ceased. In one-third of the cases exploratory operation for liver abscess was tried with negative results, but the patients recovered under ipecacuanha, and Prof. Rogers said this drug should be administered before operative procedures whenever there was a doubt about abscess having been found in the liver.

Sir Patrick Manson said ipecacuanha was a specific in amebic dysentery, but useless in the bacillary form. It had too often been given in insufficient doses or not continued long enough. He gave large doses for a week followed by smaller ones for at least a month. In amebic

hepatitis its accidental use had given him some success, and in future he would use it in threatening abscess of the liver.

Sir L. Brunton suggested that ipecacuanha killed the amœba and that the leucocytosis might be due to the irritation of Peyer's patches by the dysenteric process.

Dr. Anderson said he had found that chloral given with the ipecacuanha greatly lessened the distress caused by the nausea and vomiting. Chloral he found much better than opium for this purpose.

Mr. Cantlie remarked that the temperature very often fell and the symptoms disappeared in cases of hepatitis after merely putting a needle into the liver.

Prof. Rogers having made some remarks in reply, read another paper on a short fever which he thinks should be differentiated from malaria or continued fever, as which it has hitherto been returned. From a study of 1,350 consecutive cases of fever in Calcutta he has separated this type by the blood changes and symptoms. It begins with severe headache and pain in the back and limbs, lasts six or seven days, and may be mistaken at first for typhoid, as the pulse is slow relatively to the temperature, contrasting with that of malaria. This seven-day fever occurs in the later hot weather and early monsoon months in Calcutta and declines when the malarial rise takes place at the close of the rainy season, the two fevers making one curve through both seasons, and so have been regarded as one. The seasonal prevalence differs from influenza. It has been regarded as dengue, but the temperature curve and other characters are very different. It has probably been confused with both dengue and malaria.

Dr. Anderson said this fever reminded him of a common type in the Northwest Province, called "ardent fever," in which quinine was useless but cold sponging and bromides relieved.

Sir P. Manson said there were many different types of fever in India and this was one. He thought them protozoal —not bacillary.

Obstetricians have been somewhat preoccupied with surgical procedures. At their society Mr. J. D. Malcolm has strongly advocated the removal of the cervix in hysterectomy. He argued that when left with the blood supply partly cut off and its narrow central tube lined with mucous membrane, the cervix offered a favorable nidus for the development of microbes in the divided uterine tissues, while the provision for drainage of discharges was imperfect. This view was controverted by other speakers. Mr. Doran said the cervix was an important part of the pelvic floor and it might be that not only the cervix but a little more of the uterus should be spared. Long after-histories were important and by them he had shown the value of the so-called sub-total operation in sixty cases. Dr. Amand Routh said he, too, was not convinced by Mr. Malcolm's arguments. He did not think the blood supply was cut off nor that the cervix when left tended to degenerate. The mortality of panhysterectomy was undoubtedly larger. Pozzi's statistics of 1,000 collected cases showed a mortality of 10.4 per cent. against 7.4 per cent for the sub-total operation. It was also certain that the cervix had an internal secretion. If organs were removed on account of possible future dangers, where should we stop? Dr Eden said he had been satisfied with both operations, but preferred the sub-total except in special circumstances. He was not convinced by Mr. Malcolm's arguments. The President, Dr. Herbert Spencer, said he had performed many total abdominal hysterectomies to the entire exclusion of partial operations for the past six years. He still held that the total operation, performed by Doyen's method, was best. It provided drainage, gave security against injury to the bladder or ureters, and against unrecognized hemorrhage, it removed the cervix, which might become infected, slough, or develop malignant disease; further, it was less likely to be followed by intestinal obstruction. The supposed advantage of the internal secretion and slight shortening of the vagina could not be set against those advantages.

Another operation occupying obstetricians is Döderlein's subcutaneous pubiotomy, which seems an important improvement on Gigli's open incision of the os pubis as a substitute for the rather unsatisfactory symphysectomy. The subject has been brought before the Royal Academy of Medicine in Dublin, where the school of midwifery has so long held a reputation second to none. Dr. M. J. Gibson of the Coombe Hospital related three cases. The patients refused cesarean section but had no dread of the minor proceedings and neither of them subsequently showed any difference from a normal labor. All three infants were suckled. The advantages over symphyseotomy were stated to be that the pelvis is prevented by the undivided soft parts from springing suddenly apart, the bladder and urethra are less liable to injury, and the operation is more easily and more rapidly performed. It is a mode of overcoming the difficulties of the lesser degrees of contraction of the pelvis without injury to mother or child.

The Master of the Rotunda, Dr. Hastings Tweedy, detailed a case of a primiparous woman whom he had delivered of a living child through an internal conjugate of 6.5 cms. at full term by this operation. Hemorrhage had been very severe with considerable collapse. Delivery had to be hastened on account of prolapse of the cord and therefore the operation was done. Laceration of the cervix, perineum, and soft parts between the severed bones required catgut sutures. The patient left hospital in the ninth week with a living child.

Sir A. V. Macan remarked on the ease with which the operation could be done. There was nothing in it to deter anyone who had been through the Dublin school and it gave the country practitioner the chance of saving mother and child when forceps had been tried and failed.

Dr. Neil said the risk of sepsis was less than in induction of premature labor, and Dr. Alfred Smith said the operation had come to stay.

Dr. Jellett suggested that there were two classes of cases, those in which there was reason to believe forceps would fail and those in which forceps had been tried and failed. The ease with which pubiotomy was done would tend to diminish mortality.

Dr. R. D. Purefoy (President) said cesarean section in some cases could not be superseded. The danger of pubiotomy, had, perhaps, been passed over too lightly. Injury to the bladder had been recorded, a fatal case from hemorrhage had occurred in Vienna. Agreeing as to the value of the procedure, he still wondered if the locomotive powers of the patients had been satisfactory afterwards or if time enough had elapsed to determine that point.

In reply it was stated that the bladder was not so closely connected with the os pubis that tearing would result unless there were adhesions from previous puerperal sepsis, and the undivided soft parts gave additional protection. If hemorrhage could not be stopped by compression the wound could be opened and the source of bleeding found. The operation was safer than cesarean section up to a conjugate above 6.75 cm. It was the easiest plan for the practitioner far from skilled assistance.

Dr. R. R. Rentoul lectured on Monday at the Institute of Hygiene on "Woman's Health: Our Greatest National Asset." He vigorously denounced our neglect of this subject, as well as women's increasing desire to avoid the duties and responsibilities of motherhood. He declared that the child-hating married woman was a demoralized person whose desires were limited to a rich husband, a flat, a poodle, and a maid-of-all-work. She was a menace to the race, while the mentally healthy woman represented the best thing in life—motherhood. He advocated drastic reform of the marriage laws, encouragement of the healthy, and discouragement of the unhealthy to marry. He proposed to raise the marriageable age to 25 for men and 21 for women, to require a prenuptial medical certificate of good health, to make it illegal for diseased persons to marry, to abolish actions for breach of promise where disease existed, to prohibit paupers and vagrants from marrying, to tax bachelors, to reduce taxation to those who had small incomes and large families. There is a program that even the present government, which seems bent on destruction, might consider beyond its power. Dr. Rentoul further blamed the profession's leaders for having increased puerperal mortality by degrading the practice of midwifery and handing it to an inferior order.

The Jacksonian Prize for 1906 was last week awarded to Mr. Donald John Armour. The subject was the diseases and morbid growths of the vertebral column, spinal cord, and canal, which are amenable to surgical operations. The subject for 1908 was chosen, viz., diseases of the colon relievable by operation. The next Triennial prize is to be on the lymphatic and hemolymphatic glands, especially as to their changes in infective processes.

Birmingham City Council on Tuesday decided to establish a sanatorium for consumptives on a site costing £17,000. Accommodation for forty patients, who will be kept under observation after leaving will be provided. A minority opposed the scheme on the ground that the treatment is in the experimental stage, and it would therefore be better at present to board out patients in private sanatoria.

We are all regretting here the death of Dr W. H. Drummond, the Canadian poet and physician. I say all; assuredly that will be true of those who know his "Habitant" and other pieces so racy of the soil. His "Docteur Fiset" is a favorite with many who know that only. He was born in Ireland, but was taken to Canada in childhood, and became in every way a true Canadian. You probably know his career as well as we do.

Dr. William Henry Ransom, F.R.S., consulting physician of the Nottingham Hospital, died on Tuesday evening. He took the M.D. of the London University in 1850. He was among the Senior Fellows of the Royal College of Physicians, his election dating 1860, and he served on the Coun-

cil 1891, 1892, and 1893. In 1870 the Royal Society elected him a Fellow.

Dr. Edward Ferrand Astley, J.P., died on the 12th inst., in his ninety-sixth year. He was for a long time physician to the Dover Hospital. He took L.R.C.S. Ed. in 1833 and M.D. the next year. He did not join the College of Physicians until 1860.

OUR BERLIN LETTER.

From Our Special Correspondent.

THE DEATH OF VON BERGMANN—DISCUSSION OF THE SPIROCHETE QUESTION.

BERLIN, April 5, 1907.

THE physicians of Berlin are still mourning the loss of the eminent surgeon Ernst von Bergmann. What he was in the medical life of the city was well shown only a short time ago when he celebrated his seventieth birthday, apparently in perfect health. It is now generally known that some time ago he diagnosed his own case as one of carcinoma of the rectum, and even in his clinic made his own symptoms the subject of a discussion of this malady. For some time he continued at his manifold and arduous duties, until early in this year to his great sorrow he was compelled to give up his lectures on account of the severity of the sciatic pain from which he suffered. He then delivered a farewell address and went to Wiesbaden, where finally symptoms of total intestinal obstruction supervened. He was operated on by his pupils, Schlange and Borchard, but without success. On March 29 an impressive funeral service was held at the scene of his labors, at which the Crown Prince was present.

An interesting series of discussions on the spirochete question have been held at the recent sessions of the Berlin Medical Society. These were started by two papers, one by Blaschko, entitled "Observations and Demonstrations on the Spirochete Question," and the other by Benda on "The Critical Consideration of Levaditi's Method of Silver Staining, with Demonstrations." Blaschko opposed the statement that has been made by other observers that non-medullated nerve fibers in the organs are stained by Levaditi's silver impregnation method and may be confounded with the *Spirochæta pallida*. He said that non-medullated nerve fibers did not stain at all by Levaditi's method, and that it was out of the question for a trained observer to confuse elastic fibers with spirochetes. He had discovered spirochetes only in syphilitic tissues, and in twenty-five chancres he had found the organisms always only in one spot, and there in great numbers. According to the direction in which the sections were cut the cluster of spirochetes would be discovered or not. The spirochetes are not found in the cells, but lie in the interstices between them, and appear to wander in a direction parallel to the fibrils of the tissues. They also are disseminated through the lymphatics and blood, and often occur free in the lumen of the blood-vessels. The chancre is formed as the result of toxins given off by the organisms.

Benda said that he considered a criticism of the Levaditi silver stain justified because in all such methods depending on impregnation with metals it was difficult to determine the conditions under which the staining took place. In some instances the method was effective in demonstrating spirochetes, but in others doubts were justified as to whether the structures seen were spirochetes or not. Cell boundaries or the edges of erythrocytes could easily be distinguished from spirochetes, although these structures had been spoken of in this connection by some observers, but the end bodies of Krause of the nerve fibers in striated muscle might give rise to error as well as certain fibrils of undetermined nature in the central nervous system. Non-medullated nerve fibers were not stained by the method, and of the medullated fibers only the larger ones, so that the size of the stained structures indicated whether they were spirochetes or nerve fibrils. Against the objection that spirochetes could be stained in the tissues only by one method he offered an observation made on unstained sections of congenital syphilis of the liver, which he examined by ultra violet light. It appeared that certain giant cells without nuclei in the gummata were composed of a mass of fibers and granules apparently representing degenerated spirochetes.

In the discussion, Hoffman presented four questions. (1) Is the silver spirochete a true parasite and not a component of the tissues? (2) Is it identical with the spirochete found in smears? (3) Is the spirochete the causative agent in syphilis? (4) What is its significance in practice? The first question he thought should receive an affirmative answer, since the spirochetes could be found in the lumina of veins, in the testicular canals, and in epithelium, but only where syphilis existed. Other spirochetes, for example, those of fowls, can be demonstrated by the same method. The difference between the structures stained by the Levaditi method and the Giemsa method is easily explicable, owing to the nature of the procedures. In the process of fixation and imbedding in paraffin a considerable amount of shrinkage takes place, and in the Levaditi method the silver is precipitated on the organism in minute granules, whereas the Giemsa stain colors the spirochete itself. In regard to the question as to whether the *Spirochæta pallida* is the cause of syphilis, important information might be gained by resorting to dark ground illumination. In most cases by this means it was possible to demonstrate the living *Spirochæta pallida* in early chancres, secondary papules, etc. The importance of this lay in the fact that the diagnosis of syphilis could now be made without waiting for the appearance of the roseola.

Saling looks on the *Spirochæta pallida* as a harmless parasite, occurring incidentally also in syphilis, and considers that the silver spirochetes are artefacts formed of nerve fibrils, elastic fibers, etc. It may be found everywhere where degeneration is going on, and degeneration can always be taken for granted in syphilis, even in the primary lesion. As a reason for believing that the necrosis may have a direct connection with the occurrence of the silver spirochetes it may be pointed out that in acquired syphilis, that is, in the organs of adults, which are more resistant to necrosis, the silver spirochetes are found but rarely, and they have not been discovered in the organs of infected apes, whereas they are abundant in macerated fetuses and in foci of necrosis not caused by syphilis; for example, in the spirillosis of fowls. The producers of this disease are spirilli that occur in the blood, but not in the tissues. If necrosis is present, however, the spirochetes are found also in the latter. When spirochetes are seen free in the lumina of vessels it may be alleged that these appearances may be caused by tangentially cut endothelial cells, that they may have been displaced by the microtome knife, that the edges of red blood cells may contract into spiral forms and take up the silver, or that many varied constituents of macerated tissues may be detached and transferred mechanically into the interior of the vessels. The speaker's strongest argument against the identity of the silver spirochetes with the *Spirochæta pallida* was the fact that by inoculation with street dust he had been able to produce a keratitis with silver spirochetes that were only nerve fibrils.

Bab had been able to prove through the method of the deviation of the complement that the *Spirochæta pallida* was the cause of syphilis, for organ extracts free from spirochetes were free from antigen, while organs containing spirochetes also possessed antigen. He had found silver spirochetes only in syphilitic tissues, and he was also of the opinion that they could not be either nerve terminations or elastic fibers.

Friedenthal pointed out especially the differences in size of the various spirochetes. He was of the opinion that the silver spirochetes were only nerve ends, and stated that by this method he had been able to demonstrate about cells minute nerve fibers which were no larger than the spirochetes.

Ort demonstrated preparations to show that silver impregnated bacteria always seem larger than stained specimens. What Saling regarded as maceration in syphilis was a coagulation necrosis, that is, the opposite of maceration, and therefore Saling was in error in stating that the tissues must be macerated in order for the silver spirochete to appear. The variations in size also were no argument against the validity of these structures, for such differences occurred in all microorganisms of the same species. The argument that the spirochetes occurred only in certain spots was unimportant, for tubercle bacilli, for example, do the same thing. Ort considered that the silver spirochetes were not artefacts.

Hoffman opposed to Saling's statements the fact that by means of the dark ground illumination he had been able to discover spirochetes in the blood taken from the finger of a child with hereditary syphilis. He had also been able to obtain positive results on inoculating monkeys with syphilitic virus from the cornea of the rabbit. The so-called rabbit syphilis described by Siegel was not syphilis at all, but sepsis.

The discussion continued for some time longer and several other speakers expressed their opinions. It appears to be settled that the spirochete is not an artefact, but, according to the views of those taking part in the debate, proof that it is the cause of syphilis is still lacking.

Identical Finger-Prints.—Two men tried recently for petty offenses in South Africa were subjected to the usual finger-print records, and a subsequent comparison of these records showed that they were identical in every line and curve.

Progress of Medical Science.

New York Medical Journal, April 27, 1907.

Cystoscopy in Tuberculosis of the Urinary Tract.—Willy Meyer finds this method of diagnosis absolutely necessary. It should be preceded by palpation, examination of the urine and its centrifugal sediment for bacilli, but should itself precede the use of tuberculin. We should always think of a descending tuberculosis when a patient, especially a younger one without any gonorrhea or instrumentation, suffers from painful micturition with unilateral lumbar pain and sudden frequent urination in small quantities with the crucial test of bacilli in the urine, yet some of the foregoing symptoms are misleading in the earlier stages, as experience shows. In the more advanced cases cystoscopy is often impossible, as the bladder will not tolerate a sufficient amount of urine to enable us to proceed, and the vesical ulcerative catarrh is often so pronounced that a preliminary preparation of the bladder is imperative. This should consist in gentle irrigation with very small amounts of sterile boric acid solution two or three times weekly, frequently injected and allowed to run out, followed by bichloride solution or iodoform emulsion. The bladder should now be forced to contain more than 120 to 150 c.c. of boric acid solution. The author describes in detail his method of procedure. The coexistence of prostatic tuberculosis may render cystoscopy impossible. If the irrigating cystoscope is used, the effect of bleeding from the neck of the bladder may be readily overcome by having an assistant slowly inject the boric acid solution through the afferent tube while passing the instrument over the diseased area. This keeps the prism clean during the procedure.

Severe Ocular Pain Associated with Grippe.—The essential features of the four cases reported by J. T. Krall are thus summarized: There was a distinct history of endemic influenza vera in all four cases, two of which were males and two females, ages twenty-four to thirty-two years. From the second to the sixth day of the disease there developed sudden excruciating pain in the eyeball, affecting one in the right and three in the left eye, lasting from two to five days, gradually subsiding. At no time during the course of the disease were there any symptoms of inflammation of the eyeball or its appendages, no pain on movement of eyeball, no tenderness on pressure over parts supplied by the trigeminus, no hyperesthesia or vasomotor affections, such as pallor or coldness, or redness, heat, or edema, and no trophic phenomena. In one case there was severe deep-seated boring headache, associated with nausea and vomiting. Temperature ranged from 99° F. to 103° F. The examinations of the urine were practically negative. No examination was made for the Pfeiffer bacillus. The disease was followed by physical weakness and mental depression. The author believes that the lesion in these cases was neuralgia of the ciliary nerves. The way in which the bacillus causes it is still a matter of discussion. It has been referred to the irritation of those terminal branches of the trigeminus which are situated in the sinuses in the vicinity of the nares. It may be due to a blood toxemia acting on the nerve centers or nerve fibers, no true inflammation having taken place.

Some Application of the Roentgen Rays in Dermatology.—R. H. Boggs gives his experience with *x*-ray therapy in eczema, acne, psoriasis, keloid, cutaneous tuberculosis, and alopecia areata. Concerning its employment in eczema, he says that it is certainly not necessary in the acute form unless it be to control the pruritus, otherwise unrelieved, nor in most forms of subacute eczema. It is, however, useful in many chronic cases rebellious to treatment. The good effects are most marked in the squamous form. It requires more intense radiation to relieve the pruritus, and there is a greater tendency to recurrence than in any other form of the disease. After a few applications the discharge and itching cease and the desquamation is arrested. In weeping eczema the desquamation usually ceases after four or five treatments. In eczema of the legs, with a complicating varicose ulcer, radiation should be entirely different in application from that employed in the squamous form, as there is marked difference in the vitality of the tissues. The rays here relieve the eczematous condition greatly increase local metabolism, and assist the other methods of curing the ulcer. The author says, with reference to keloid, that the *x*-ray therapy has been more successful than any other method up to the present time. However, by the Roentgen method it requires considerable time to remove a keloid, and rays of such character as to stimulate normal tissue processes and promote absorption should be employed. Rays which are very destructive, if given in large amounts as in carcinomatous tissues, are contraindicated in the treatment of keloid. It has been advocated by some to have the keloid removed and then give a series of treatments. This shortens the length of treatment, but the author would not advise the removal unless the tumor is extensive, as cutting a keloid occasionally stimulates the activity of its growth.

An Unusual Symptom in Chorea.—Three cases of chorea are reported by G. F. Price, in which excessive secretion of saliva with drooling was a prominent symptom. The patients were a boy of twelve years and two girls of fourteen and six years respectively. In each case the patient had had one prior attack of chorea. All were severe, and two had distinct mitral murmurs. No history of rheumatism could be obtained in any of the cases. The author believes that the symptom is of purely mechanical origin, the movements of the tongue and of mastication exciting the salivary glands to increased activity and the involvement of the tongue, jaw, palate, and pharynx so interfering with swallowing that the saliva is retained in the mouth or drools from the corners. Under the use of the usual remedies for the chorea, the symptom mentioned was relieved in all the cases reported.

Journal of the American Medical Association, May 4, 1907.

Infantile Atrophy of Intestinal Origin.—D. L. Edsall discusses the pathogenesis of infantile intestinal atrophy and offers the theory that it is the result of disorder of the ferment function of the intestine. That is, when the proteid of the ingested food is progressing in the breaking down or fragmentation necessary for its reconstruction into homologous form, the final attack by the ferment of the intestine does not occur or is ineffectual, and the rebuilding into the patient's tissues fails or is imperfect, hence the atrophy. The foreign protein may be either incompletely fragmented and the reconstruction therefore rendered impossible to the extent of producing a homologous protein, or the intestinal ferment failing or reduced, reconstruction would also fail. This hypothesis is consistent with the fact that the difficulty lies in the utilization of the milk of a foreign species. There is no good evidence, he declares, that infants ever fail to assimilate human milk unless they are desperately ill, provided that the milk is not so rich as to upset digestion or so poor as to be insufficient; and provided also that the mother or nurse is not in such a physical or emotional state as to render the milk unsuitable. He has tested his hypothesis by studies of the proteolytic power of the intestines obtained at autopsy in three cases of children dying of typical progressive atrophy; also in three control cases of persons dead with extreme emaciation due to other causes, and also in two cases of older persons with continuous and final extreme emaciation for which the autopsy showed no cause. His method of investigation is given in detail, and the results in the cases of infantile atrophy appear to support his theory, inasmuch as they show a great reduction or entire loss of proteolytic power in the intestinal mucous membrane. The control cases show a much greater proteolytic power. The two older patients were stuporous and were fed by the stomach tube. In both, the intestinal extract showed no proteolytic action, but, contrary to the infantile atrophies, the extract of the gastric mucosa showed little, if any, evidence of the presence of pepsin. The suggestion of Pawlow that in such cases the lack of psychic stimulus to the production of digestive ferments may play a part, is referred to, and Edsall thinks that here also there is a field for study.

Hemolysis in Pernicious Anemia, Augmented by Urinary Retention.—H. A. Freund reports a case very similar to that reported by Cunningham (*Annals of Surgery*, February, 1907) of pernicious anemia complicated with urinary retention. He does not, however, accept Cunningham's view that the urinary retention was secondary to the relapses of the anemia which caused weakness of the bladder musculature. On the other hand, he is inclined to think that the enlarged prostate, which was present in both cases, was primarily responsible for the urinary retention, and that following this there was a retention and absorption of the hemolysins which failed to be excreted, with consequent changes in the course of the disease. When the poison that is normally being excreted from the kidneys is added to that in the general circulation, increased hemolysis is to be expected. He discusses the origin of the hemolysis in pernicious anemia and remarks that his observation and that of Cunningham suggest new questions for profitable study: the constancy of hemolysins in the blood and urine in pernicious anemia, together with their relation both quantitatively and qualitatively; the absorbability of these substances, and the presence of the products of hemolysis in the urine. A method for

estimating hemolysins that will give uniform results is also to be desired.

Erythema Induratum (Bazin).—The erythema induratum of Bazin, according to L. Weiss, stands about third in the list, and is a very important exponent of the group of cutaneous tuberculides of Darrier, being preceded by lichen and acne scrofulosus and the papulonecrotic tubercle. In more than half the reported cases it has been proved to be associated with tuberculosis, and in a very few cases the tubercle bacillus has been found in the lesions. In other cases inoculations in guinea-pigs have given positive results, while in still others the tuberculin reaction has been demonstrated on the patient. The characteristic features are the formation of subcutaneous deep-seated nodules, more easily recognized by touch than by sight, and developing into hard, deep-seated indurated nodes not adherent to the skin at first, but becoming so later. The skin is at first purplish, then as the nodes become larger and work toward the surface it changes into a dull violaceous hue. The size of the nodules varies from that of a cherry to even double that size. Their development is slow, and when they ulcerate, which is seldom, necrosis begins at the summit of a nodule, rarely more than one, and is attended with a scanty, semipurulent discharge. The scarring and pigmentation is not so pronounced as that of ulcerous scrofuloderma. It occurs chiefly in young females, occasionally in older ones, and very rarely in men. It is usually on the legs, but in the case reported by Weiss it occurred also on the nates, which, he thinks, has not been before recorded. There was a stormy tuberculin reaction in this case. The histological features were much the same as those found by other investigators; an atrophic degeneration of the subcutaneous fat tissue, and formation of giant cells with radiating nuclei and epithelioid cells and endothelial proliferation of the vessels. The symptoms disappeared spontaneously. As regards the differential diagnosis from erythema nodusum, he remarks on the brighter color and more inflammatory and painful character of the latter, the rarity of the lesions breaking down and the manner of their disappearance resembling that of an ecchymosed contusion, as contrasted with the more chronic, slighter pain, and inflammatory symptoms and more evanescent disappearance of erythema induratum. The differentiation from syphilitic gummata, which it resembles very closely, can be made by the multiplicity of the nodes in erythema induratum, the chronic course and systemic symptoms, and the therapeutic test with specific treatment. The confusion, with lepra to which it bears a far-away resemblance, is not very imminent.

Interesting Gynecological and Obstetrical Cases.—T. S. Cullen gives detailed reports of several cases of more than usual gynecological or obstetrical interest. The first is that of a patient from whom he removed a cystic uterine myoma weighing eighty-nine pounds. The patient had been aware of its presence for twenty years, and notwithstanding its size was able to do her household duties up to three weeks before the operation. Her principal inconvenience had been the danger of suffocation if she turned on her back in bed. Though considerably larger myomatous uterine tumors have been reported, this appears to be the largest successfully removed. Owing to exigencies of the case no part of the abdominal wall was resected, but the tissues contracted remarkably well, and the patient rapidly regained her strength and suffered much less inconvenience than might have been expected. This tumor was nourished mainly from the omentum, some of the vessels being 7 or 8 mm. in diameter. Another case is reported of a pedunculated myoma weaned away, so to speak, from the uterus, presenting the rather unique feature of a rope of omental vessels to the tumor 6 cm. in diameter. In the hardened preparation after removal, some of the individual blood-vessels are 1 cm. in diameter. A considerable series of such cases have been studied by Dr. Kelly and the author, and will be published at some future date. Other cases reported are one of death of fetus with suppuration and anterior perforation of the uterine wall, the pus being walled off by adhesions and the patient recovering after supravaginal hysterectomy; one of abdominal pregnancy in which a seven or eight months' fetus was carried for four years without causing serious symptoms, and one of chorioepithelioma with apparent recovery after hysterectomy. The article is illustrated.

Treatment of Traumatic Gangrene.—Van Buren Knott defines traumatic gangrene as that variety of gangrene following severe crushing injuries of the extremities complicated by virulent and often fatal sepsis. He discusses the unsatisfactory course pursued in many cases and gives his present method of treatment as follows: Being confronted with a case of traumatic gangrene of an extremity, estimate as exactly as possible the line between the diseased and healthy soft parts. Under anesthesia make a most careful and complete disinfection and cleansing of the skin, puncturing all bullæ and removing all discharges, envelop the gangrenous area in a sterile towel up to the line selected, and then, at this point, make a circular amputation, cutting through soft tissues and bone at the same level. Ligate carefully all bleeding points, including none of the perivascular tissue in the bite of either the forceps or the ligature. Leave the wound open, not introducing a single suture, and apply moist dressings of gauze saturated with salt solution, these dressings to be changed from two to four times in twenty-four hours, as the circumstances of the particular case demand. After seven to ten days, if the wound is perfectly clean and the condition of the patient favorable, the classic circular amputation may be made by dissecting up the flap already outlined and sawing the bone at the proper level. If for any reason the circular method may seem undesirable, any other procedure may be substituted, but in the class of cases under discussion a typical circular amputation will be found entirely satisfactory.

Eyestrain and Epilepsy.—H. O. Reik argues for the importance of eyestrain as a causal factor of epilepsy, and quotes extensively from Dr. Spratling's work on "Epilepsy and its Treatment," as giving unintentionally valuable evidence of this possibility. Reik says that if only 1 in 100 epileptics can be cured by relieving measures for eyestrain it would practically double the number of cures of epilepsy. He reports four cases in which epileptic attacks appeared to be entirely suppressed for considerable periods by the correction of optical defects, and also the notes of two others observed by Dr. J. F. Crouch of Baltimore. In some of these cases at least the temporary disuse of correcting glasses seemed to increase nervousness and to bring on a tendency of the original attacks. He does not claim, therefore, to remove the original nervous instability altogether, but to have removed the exciting cause. "The removal of the reflex excitant does not, of course, cure the disease; the predisposition is always there, and if the patient be again subjected to eyestrain the attacks will probably recur; or if the eyes be kept in perfect condition some other exciting factor, such as a pregnancy shock or great anxiety, may precipitate a convulsion." It is nevertheless necessary that the eyes, like all the other special organs, should be thoroughly examined by experts to insure the utilization of every possible means of relief from the attacks and for preventing aggravations of the underlying unstable conditions by such irritating factors.

The Lancet, April 20, 1907.

Scopolamine Poisoning.—A. W. Moore reports the case of a girl of four and a half years in each of whose eyes one drop of a one per cent. solution of scopolamine was dropped. The child soon became restless, and in one hour she was definitely delirious. Color remained good. The pulse was 80 and temperature normal. Later the delirium became more marked and was of a busy, happy type. She tried to get out of bed, had various hallucinations of sight, would warm her hands before an imaginary fire, etc.; would not eat, but took a little milk. This state lasted about eight hours, gradually ceasing during the night, although the child did not sleep. The next morning she seemed more rational, quiet, and obedient. About twenty-four hours after the instillation of the eye drops drowsiness came on. If the child was awakened she would immediately turn over and go off into a deep sleep. There was, however, no real coma, and in about two hours the child seemed well. A small injection of strychnine was given when she became drowsy. There were no disagreeable after-effects.

Some Indications for the Treatment of Cholera.—K. B. Choksy enumerates under this heading the destruction of the virus *in situ*, and has had good results with cyanide of mercury. He gives one-tenth of a gram in an ounce of syrup and water every two or three hours, according to the stage of the disease and frequency and character of the motions. The loss of fluid to the system is made good by saline transfusion, hypodermoclysis, or enteroclysis. The circulation is maintained and the renal function reestablished by the following, every two to four hours: Sodiosalicylate of caffeine, 2½ grains; sparteine sulphate, ½ grain; liquor atropinæ (B.P.), 1 minim, the whole in 20 minims of brandy. All food and dietetic alcoholic preparations must be cut off. Hot coffee, without milk or sugar, is freely given as often as the patient asks for a drink, and it quenches thirst far better than cold solutions. Then sweetened arrowroot may be given and milk gradually added. The patient must be carefully watched during the stage of reaction. An alkaline mixture with digitalis and nux vomica generally does well

here. Symptomatic treatment may be required for occasional persistent vomiting, diarrhea, prostration, or sluggish kidneys. Dry cupping is of special service. The foregoing plan of treatment has been tried in 395 cholera patients, 226 of whom were treated during the epidemic in India, 1900. With the exception of some 46 sporadic cases, the rest were treated during epidemic periods. The mortality rate was 51.39 per cent. as contrasted with a rate of 89 per cent. in the surrounding regions.

The Lymphatic System of the Stomach.—In the course of an elaborate article on this subject, J. K. Jamieson and J. F. Dobson note that the study of the spread of malignant disease of the stomach to the other groups of abdominal lymph glands is much facilitated by an accurate knowledge of the course of the lymphatic vessels. The groups of glands usually found affected in the late stages of the disease are the glands at the hilum of the liver, the glands around the celiac axis, the superior mesenteric glands, the biliary glands, the mesocolic glands, and the lumbar glands. There are no direct vessels connecting the stomach or any of the gland groups receiving direct vessels from the stomach with the glands at the hilum of the liver. These glands receive vessels from the liver and transmit them to the right suprapancreatic and biliary groups. In advanced carcinoma of the stomach they must become diseased either by retrograde infection along their efferent vessels or secondarily to a growth in the liver. The paths by which the middle suprapancreatic glands are affected can be easily followed: from the coronary groups, the subpyloric group, or the splenic group. They transmit efferent vessels not only to the receptaculum chyli, but also to the lumbar glands around the aorta and vena cava. It is obvious that these glands may readily become diseased by the direct transmission of cancerous emboli from the middle suprapancreatic glands. The superior mesenteric glands receive vessels from the subpyloric group. This group is frequently diseased, and infection will spread readily along its efferent vessels. It is not necessary to assume that the glands lying below the level of the celiac glands become diseased by means of a process of retrograde infection or secondarily to obstruction of the thoracic duct, or to the development of metastases in the liver. There are direct paths, as the authors have shown. The affection of the mesocolic glands is not so readily explained. They may become diseased by retrograde infection from the superior mesenteric glands to which their efferent vessels run; a more likely explanation is that the primary disease has spread from the stomach into the gastrocolic omentum, possibly to the colon or into the mesocolon, thus invading the lymphatic area draining into the mesocolic glands. The biliary group of glands receive direct vessels from the upper part of the pylorus, and by this path they may become affected.

British Medical Journal, April 20, 1907.

Oxyuris Vermicularis.—A. N. Davies calls attention to the use of quassia in an enteric pill, two grains coated with keratin. It is a useful adjunct to the employment of other remedies.

Salicylism and Epistaxis.—Referring to recently reported cases of nose bleed in grippe cases, E. Leach is inclined to think that the former may have been due rather to salicylates given than to the grippe poison. This manifestation of salicylism may be unattended with any head or kidney symptoms. It may be that only impure specimens of the salicylates cause nose bleed.

Hernia of the Gall-bladder.—A case is reported by H. B. Hanson whose patient was a Hindoo woman of fifty years. On the right side of the abdomen was a soft, round, tender swelling, diameter one and one-half inches, its center two inches to right of midline, and three inches below the margin of the ribs. She complained of having had indigestion for the last two months, and said that the swelling had appeared suddenly one month previously, when she was doing some heavy grinding. Pain, she said, had been present only ten days, but histories in Indian women are very unreliable. On operation below the subcutaneous fat and beneath the abdominal muscles was the fundus of the gall-bladder enclosed in a peritoneal sac. The edges of the stricture round the neck, formed by the abdominal muscles, were snicked, a few adhesions between stricture and sac and bladder and sac separated, most of the latter removed, and the fundus returned into the abdomen. Both the right and left lobes of the liver were enlarged. The stitches were removed in twelve days and the patient discharged two weeks later.

Intestinal Origin of Leprosy.—H. L. Clift notes that in certain parts of China where leprosy is common, there are lepers who sell eatables on the street. They and the food they sell are surrounded by flies, who come in contact with their sores. These flies may settle on fish, which in turn becomes contaminated. It makes, when putrid, an excellent nidus, and if eaten half-cooked some of the bacilli must certainly enter the gastroenteric canal in a living state. Now if this is true of fish, why is it not true, the author asks, of other eatables? Does not this explain, he continues, why Hutchinson's theory sometimes appears so plausible and at other times appears to break down? He means that the practice of eating putrid fish in a more or less raw condition is not essential to the spread of the disease. The bacilli can reach the intestine through the medium of other food also. Leprosy may be fairly common in a district and yet very little food be eaten there. Comparing the disease with tuberculosis, the author notes that in the former the bacilli are carried by leucocytes which lose their amœboid movement. In leprosy the bacilli have been found occasionally within white blood corpuscles; perhaps the lepra cells were originally leucocytes? The taking of common salt really seems to benefit the patient; this may be because of increased hydrochloric acid, which helps the digestive juices to destroy the germs, and the system is thus relieved from ingesting more *living* bacilli. Three points leprosy has in common with tuberculosis: There must be a predisposition, natural or acquired, in the patient; both may have a long incubation period; and both are incurable—the patient is said to be "cured" because treatment and environment have "stayed" the disease.

Calcium Salts in the Blood and Tissues.—The part played by the calcium salts in the blood and tissues is discussed by W. B. Bell with special reference to their influence in regard to female genital functions. He also adds a description of a simple method of quantitative analysis, for which he has described a special apparatus. There are, he says, three calcium periods in a physiological sense. First, the period of growth, when the young person or animal requires all the calcium salts obtainable for the formation and growth of the bony skeleton. Secondly, the period of reproduction, when a calcium equilibrium as regards growth is reached, and an "excretion" of the excess occurs. This is most obvious in the reproductive processes of women, when large quantities of the calcium salts are first given up to the fetus and then for the formation of milk, during which the menstrual function is in abeyance. Some observations the author has made seem to show that pregnancy is terminated when the fetus ceases to absorb (or receive) calcium salts from the mother's blood and a large accumulation occurs in her system, bringing about contraction of the uterine muscles. The third period is that of late life, when no calcium salts are required for the building-up processes or for those of reproduction. These salts then accumulate in the tissues, especially in the vessels (and it is interesting to note how rare this is in women in middle life), atrophy occurs, and the individual gradually declines.

Pulsus Bisferiens.—According to T. Lewis, this term is now applied to a form of palpably double pulse. It has two beats, the second of which is really a reinforcement of a prolonged systole. If we define this type as one which is double to the finger, it follows that every observer will have a standard of his own, dependent on the delicacy of his tactile sense. The author takes as his standard a sphygmogram in which the apices of the two waves are separated by a time interval of less than one-tenth of a second, and in which the second wave is not prominent. Lewis found such a pulse in thirteen out of twenty unselected cases of aortic regurgitation. This form of pulse has been referred to as suggestive of aortic stenosis with senile arterial degeneration. A point of interest is that a double beat is frequently more easily palpable and gives a more distinct tracing on one or the other side of the body. One type occurs in those cases in which there is great enlargement of the left heart associated with or caused by disease of the aortic valves or larger arteries, but there is no constancy between the double wave and the degree of hypertrophy or dilatation. One type is associated with arteriosclerosis, but in the other type this lesion is wanting. The author's views are illustrated by several pulse tracings. The pulsus bisferiens has been observed after the administration of digitalis. It has been noted also in pericardial adhesions or excess of fluid, and, lastly, in ballooning of the aorta

Berliner klinische Wochenschrift, April 15, 1907.

The Treatment of Chronic Bronchitis with the X-Rays.—Immelmann made use of this procedure in a series of cases following the suggestion of Schilling that the *x*-rays had an excellent effect in bronchitis and bronchial asthma of the chronic type. In the patients in whom the method was applied the results were excellent, the asthma being particularly benefited. The application is made for ten minutes on the anterior, posterior, and lateral aspects of the chest, and only a limited number of expos-

ures are necessary to produce a result. In cardiac asthma and that depending on a nervous basis no effect was observed.

Physical Measures in Nervous Diarrhea.—Tobias states that all forms of diarrhea respond to physical, and especially hydrotherapeutic measures, whether they are due to anatomical changes in the gut or exist without any pathological lesion. The nervous type according to the writer seems to be particularly benefited by physical measures. Three varieties of this condition may be distinguished according to the mode of origin. In the first we have to deal with some idiosyncrasy against certain articles of food. In the second, which constitutes the principal group, any nervous excitement will bring about an attack. Fright and fear are the commonest causes, although changes in the weather are often at fault. In the last class we have to deal with some reflex irritation from neighboring organs, such as a retroflexed uterus or disturbances in the sexual apparatus. There may be other associated nervous symptoms, or the diarrhea may be the only manifestation of trouble. Tobias has found that cool half baths, preceded by a few minutes' session in a steam or light bath. The temperature should not be reduced below 24° C. Cold douches and packs are also of value, but warm baths only serve to further soften the patient. A procedure of this kind should not be continued for more than three or four weeks, and then if necessary repeated after a sufficient interval. The diet is very important, contrary to the views of many, who claim that the nervous character of the disease makes any adherence to dietary rules superfluous. The food should be nourishing and of sufficient amount. Fats are particularly useful, as well as cereals, but meats should be restricted, and spices are not to be used. Alcoholic, as well as all other cold or carbonated drinks are absolutely contraindicated. Massage and gymnastics are only of value as a help to improve the general condition.

Münchener medizinische Wochenschrift, April 9, 1907.

Endocardial Murmurs.—Geigel calls attention to the difficulty of distinguishing at certain times between endo- and pericardial murmurs. He thinks that in fresh cases of endocarditis the murmur is produced by a rubbing of the edges of the valves similar to what occurs in a pleurisy. The segments of the valves are not properly approximated owing to the presence of excrescences, and one may therefor be taut, while the other is still more or less relaxed, resulting in a rubbing of one on the other.

The Bier Treatment of Mastitis.—Zacharias finds that this procedure is an excellent one for the purpose indicated, as in a series of thirty-three cases operative interference was found to be necessary in only two, and this was due to late application of the treatment. Among the advantages attending Bier's procedure is the fact that nursing need not be stopped during the treatment, and if it is on account of pain and tenderness the secretory activity of the breast is not stopped. The apparatus is best applied about thirty minutes at a time from two to three times daily, the globe being taken off and reapplied about every ten minutes. As a rule, it was not found necessary to keep up the treatment for longer than three or four days. When applied early the method affords very satisfactory results, and although it is very simple, the writer advises against permitting the patient to apply it herself, as the results of the treatment cannot be judged by the latter.

The Treatment of Anthrax.—Barlach describes a method which he has used successfully in a considerable number of cases. A deep groove is made with the thermocautery around the pustule, and the latter is thoroughly incised with the knife. The tension in edematous areas is relieved by extensive incisions, and around the entire circumference of the pustules injections of tincture of iodine are made. The affected areas may then be covered with compresses of bichloride. The procedure stated can be quickly carried out, and does not seem to be particularly painful. The results were excellent, and are ascribed by the author to the fact that the cauterization immediately limits the spread of the infection. The iodine seems to act as an antitoxic, although in what manner the writer is not prepared to say.

Deutsche medizinische Wochenschrift, April 11, 1907.

Radiographical Findings in Apical Tuberculosis.—Vierhuff refers to the fact that although very good results with this procedure have been obtained, it has not met with a sufficiently extended reception in the diagnosis of the early lesions of pulmonary tuberculosis. In contrast to the older methods, it is possible to demonstrate both superficial and deeper foci, which would give no physical signs under other circumstances. In doubtful cases it may even assume the importance of a positive bacteriological finding. The technique must necessarily be absolutely correct, and a thorough experience is necessary in order to properly interpret the findings. The writer cites a number of cases which show that thickening in the pulmonary tissue can be demonstrated by the *x*-rays before any auscultatory or percutory signs are present. In cases where the usual physical signs disclose the presence of the lesions, its boundaries can be much more sharply defined by the rays than by any other method.

Complex Hemolysin Derived from the Pancreas.—Friedemann details the results of some recent experiments which are of considerable interest. He found that among mammals it was possible to isolate hemolysins which are analogous to the poisons found in the venom of snakes and bees. These are lecethids, and may be secured from the discharge of a pancreatic fistula. It is also possible to extract a complex hemolysin with alcohol from the substance of this gland. The active principle of the pancreas acts like an amboceptor, for it may unite with the blood cells, but can be distinguished from the ordinary amboceptors by its high degree of thermolability. The hemolytic action of this substance is also manifested against the blood cells of the same species of animal (autohemolysis). The writer concludes that the pancreas contains a poison which is characterized by a paralyzing and hemorrhagic action, and is therefore very similar to the crotalus poison.

Tetrachlormethan as a Solvent.—Wederhake refers to the dangers attending the use of certain materials necessary for the solution of drugs or for other purposes. Among these the best known are ether, chloroform, and benzine. In cases where the skin has been cleaned with ether or benzine before the application of a cautery, severe injuries have been known to result. The writer suggests tetrachlormethan as a satisfactory substitute. This substance is obtained by the action of chlorine on boiling chloroform either in the sunlight or on the addition of iodin. It may also be prepared by the action of chlorine on bisulphide of carbon. This fluid constitutes an excellent solvent for bromine, iodine, oils, paraffin, rubber, resins, and tar, and at the same time possesses the advantage of not being inflammable. It penetrates into the deeper layers of the skin, and therefore acts as an efficient disinfectant when used in conjunction with iodine in solution. The following formula is proposed for the disinfection of the hands: iodine, 1.0; solid paraffin (43° C.), 0.5; tetrachlormethan, 100.0. The results are stated to be superior to those obtained with Furbringer's method.

French and Italian Journals.

Preventive Surgery in Epitheliomata of the Appendix and Mammary Gland.—L. Longuet states that in the course of examinations of specimens of the appendix that have been removed by operation some are found that are of a distinctly atrophic type, small, firm, fibroid, and containing islands of epithelium, which remain as vestiges of the old lining. These occur in persons over forty years of age. This epithelium is very apt to degenerate into a cancerous growth. The author believes that cancer of the vermiform appendix is of frequent occurrence. He advocates a preventive operation on the appendix after the age of forty, to relieve from the possibility of degeneration into cancer. In the same manner the degeneration of the mammary gland after the menopause exposes the woman to the dangers of epithelioma of the breast, a disease that can be cured if operated on in the period of inception, but that, owing to its insidious approach, is frequently not seen by the surgeon until it is so far advanced that operation, although successful at the time, results in the end in recurrence and death. In such conditions the author questions whether we should not be justified in making a subcutaneous operation for the removal of the gland tissue after the menopause to prevent possible degeneration. The objections to this procedure are that many women never suffer from the disease, and that there is no use in submitting to a surgical procedure for a trouble that may never occur. Recurrences after operation are given by authors as from 20 to 40 per cent. of all cases operated on. The operation could be limited to cases in which there was a suspicion of coming trouble. Either cancer is a general disease with local manifestations, in which case the treatment should be serotherapeutic or constitutional; or it is local and operation is the proper resource and preventive. The operation proposed is somewhat in the nature of vaccination, which has become general at the present day. A surgical vaccination will do away with many cases of epithelioma of the breast and appendix.—*Le Progrès Médical*, February 2, 1907.

Surgical Treatment of Puerperal Pyemia.—A. Faix says that puerperal pyemia will remain with us as long as criminal abortion exists. Its frequency and severity have not been lessened by any methods of treatment that have been adopted. Bacteriology shows that the germs invade

the uterus, and pass by way of the sinuses into the venous circulation, creating endovenous lesions that favor the formation of a clot. From this clot emanate septic emboli containing bacteria on whose degree of virulence depends the severity of the infection. This may be acute, with continued high temperature and frequent chills, having a rapid course and early metastases, and ending soon in death. Another form is much slower, showing the action of much less virulent bacteria. Soon after labor there is a septic endometritis, but it is not until some weeks later that irregular chills begin, each fresh chill indicating a fresh thrombosis. The germs penetrate to the beginning of the uteroovarian and hypogastric veins, and form thrombi, which by liquefaction become sources of fresh infections through the circulation. Ligation of thrombosed veins has been successful in the sinuses of the skull and in other locations, and it seems logical to expect that it will be of service here if undertaken before there have been metastases and diffusion of the infection through the general circulation. Infection of the great veins of the pelvis and parametritis are contraindications to operation. Opitz considers criminal abortion an indication for operation. Severe infections always occur after placenta prævia, manual removal of the placenta, or artificial delivery. Pulmonary embolism contraindicates operation. If the process has been successfully resisted by the system for some time it is reasonable to suppose that the infection is less virulent, and the hope of staying it is better. There must be a heart and kidneys in good condition to justify operation. When there is a hard cord running along the infundibulopelvic ligament we may be sure that the spermatic vein is involved. Absence of edema indicates that the large veins of the pelvis are not involved. As to the side that is affected we may be guided by the location of tenderness on pressure. The veins should be denuded carefully, ligated, and the diseased portions removed. Out of twenty collected cases thirteen died and seven recovered. We should operate promptly in acute cases, later in chronic ones.—*Gazette des Hôpitaux*, February 2, 1907.

Symptomatology and Early Diagnosis of Cancer of the Cervix.—Polosson speaks strongly of the necessity of early diagnosis of the cancer of the cervix, since delay allows the patient to pass into the inoperable stage. Cancer in the cervix occurs much earlier than cancer of the body of the uterus, being most frequent from forty to fifty years of age, and occurring as early as the twenty-first year. It does not affect the general health for a long time. It does not occur in virgins and is more frequent in multiparæ, lesion of the cervix as a result of delivery predisposing to cancer. Irregular hemorrhage before the menopause, or return of hemorrhage after it should lead to an immediate examination. Hemorrhage generally occurs after connection, a simple douche, or a violent movement. When a fetid, rose-colored discharge appears, the disease is already advanced. Pain is a late symptom, resulting from compression of the nerves in an involved broad ligament. Early diagnosis depends on examination of every case that has irregular hemorrhage, and the finding of an ulcerating, vegetating mass that is very friable and bleeds easily. In some cases there is a hard cervix, in which the ulceration is found in the canal. The uterine cavity should be explored and a fragment removed for examination to aid in diagnosis when necessary. Immediate operation alone will save the patient.—*Gazette de Gynécologie*, February 1, 1907.

Treatment of Surgical Tuberculosis at the Seaside.—Riccardo Sabatucci describes the benefits of treatment of cases of surgical tuberculosis by a sojourn at the seaside as of value in improving the general conditions as well as the local ones. The observation of these cases by the author has led him to change entirely his opinion with regard to the value of early operation in such cases. He now treats them by a sojourn in the open air at the seaside. Such treatment has been given for some years in France and Italy especially. The author's experience refers to the hospital at Anzio, which is located on a point of land 400 feet above the sea, in a villa formerly used by one of the popes, surrounded by a large and beautiful garden. The greatest benefits are received in glandular and osseous tuberculosis, and in those cases that have not undergone operation. The good results are to be had in eighty-four per cent of the cases. Only immobilizing apparatus was used, with drainage and scraping when necessitated by sinuses. The effect on the blood was marked, there being found by careful examination increase in the number of red corpuscles, diminution of the leucocytes, increase of hemoglobin, diminution of polinucleosis of neutrophiles, increase of eosinophiles, and diminution of lymphocytes.—*Gazetta Medica di Roma*, December 1 and 15, 1906.

Books Received.

While the Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Book Reviews.

HANDBUCH DER SAUERSTOFFTHERAPIE, herausgegeben von Dr. MAX MICHAELIS, Universitaets-Professor. Berlin: August Hirschwald, 1906.

THIS book may well serve as an example of German thoroughness in going into detail, for we have presented here a volume of about 600 pages on the therapeutic uses of oxygen by a number of the best known medical men of Germany and Austria. The work is a manual and properly opens with an historical review of the subject from which we learn that the employment of this gas for medicinal purposes was practically coincident with its discovery. Priestly and Lavoisier both recognized the value of oxygen in restoring asphyxiated subjects. It was not until comparatively recent years, however, that the employment of oxygen in medicine was placed on a scientific basis, for it was natural that a reaction would follow the claims made for the substance as a panacea for all the ills. The chemical and mechanical difficulties which attended the production of the gas having been removed, it rapidly came into favor again as a therapeutic agent and is now quite generally employed within proper limitations. The book in question is divided into two parts, the first of which includes the physiological and experimental basis for the administration of the gas, the technique of the latter, and its indications. The second portion comprises details of its use in the prophylaxis and treatment of pulmonary diseases and in poisoning. Its employment in surgery, obstetrics, children's diseases, internal medicine, and other fields is discussed in a thorough manner and the work may be described as a most valuable book of reference in a field where such are infrequent.

LECTURES ON DISEASES OF THE LUNGS. By JAMES ALEXANDER LINDSAY, M.D., F.R.C.P. (Lond.), M.A., Professor of Medicine, Queen's College, Belfast; Physician to the Royal Victoria Hospital, Belfast; Consulting Physician to the Ulster Eye, Ear, and Throat Hospital, Belfast; The Ulster Hospital for Children and Women, Belfast, and the Coleraine Cottage Hospital; Examiner in Medicine in the Royal University of Ireland; Late President of the Ulster Medical Society and of the Ulster Branch of the British Medical Association. Second Edition. Enlarged and rewritten. New York: William Wood & Company, 1906.

IN this excellent revision of his work on diseases of the chest, the author has, with advantage, considerably elaborated a series of lectures on physical diagnosis and diseases of the lungs, wisely omitting the lectures on diseases of the heart contained in the first edition. The first few chapters the author devotes to a consideration of physical examination of the chest with reference to the lungs, and a brief discussion of radiography and radioscopy. In these chapters the author pays fitting tribute by frequent reference to the pioneer work of Laennec and Skoda on auscultation, which, as he points out, has been but little elaborated since the writings of these illustrious clinicians. A few chapters devoted to the study of pulmonary symptoms follow and within the limits of the work touch practically all of the salient points.

In his discussion of pleurisy, pneumonia, bronchitis, etc., the author is perhaps ultra-conservative, though, on the whole, little exception can be taken to the subject matter. A considerable part of the work is naturally devoted to the subject of pulmonary tuberculosis, and if one bears in mind that these lectures are not intended to replace more exhaustive treatises upon the subject, they will be found most valuable for the purpose of hurried reference. In the matter of treatment the author is somewhat old-fashioned and ambiguous. For instance, at the present day an author should be more specific and definite than to advise "suitable change of climate," "due regulation of nutrition," etc. It is probable also that many might take issue with the author's views on etiology, especially as regards "house infection" in tuberculosis. However, on the whole, the work is a valuable addition to the library of the practitioner or the student of medicine. It is adequately indexed, pleasant reading, and not too cumbersome.

HIGH FREQUENCY CURRENTS. Their Production, Physical Properties, Physiological Effects and Therapeutical Uses. By H. EVELYN CROOK, M.D., B.S., Lond., F.R.C.S., Eng., etc. New York: William Wood & Co., 1906.

THERE are very few books that come so apropos as this handy volume on high-frequency currents. This method of electrotherapy has become very popular within the last few years, among both general practitioners and specialists. While formerly a static machine was the height of a physician's electric equipment, nowadays one must possess a high-frequency apparatus in order to be up-to-date. The present volume gives a concise but quite comprehensive description of the apparatus used, the methods of application, the physiological effects, and the therapeutic value of the high-frequency currents. While the reader is supposed to possess an elementary knowledge of electrophysics, the technical parts of the subject are not so difficult that they cannot be grasped by any physician, even by beginners in electrotherapeutics. The book will repay close study and is quite sufficiently elaborate for physicians who do not wish to make electrotherapy a specialty, but who want to know what they are doing and why they are doing it when they apply the high-frequency current in their offices.

STÖHR'S HISTOLOGY, arranged upon an Embryological Basis by Dr. FRED'K T. LEWIS, Assistant Demonstrator of Embryology at the Harvard Medical School. From the Twelfth German Edition by Dr. PHILIPP STÖHR, Professor of Anatomy at the University of Würzburg. Sixth American Edition. Philadelphia: P. Blakiston's Son & Co., 1906.

STÖHR'S textbook on histology has long been considered one of the classics of German medical literature, but in adapting it to American needs the translator has arranged it on an embryological basis in order to meet the want for a book of this kind in schools where embryology is made part of the curriculum of medical studies. This has necessitated certain changes in the German text which have been made, however, with Prof. Stöhr's permission. Considerable attention has been paid to the nomenclature, the widely used system adopted by the German Association of Anatomists being employed, which favors the simplest Latin descriptive names and discards the numerous personal appellations formerly used. Since the cell constitutes the unit of development as well as of structure, it would seem perfectly rational to study histology, which is practically a study of cells or their immediate derivatives, from the developmental standpoint. And yet most textbooks on the subject are a mass of collected, independent facts which afford to the student a very confused idea of this important matter. Dr. Lewis' book may be commended as a valuable addition to textbook literature.

WOMAN. A Treatise on the Normal and Pathological Emotions of Feminine Love. By BERNARD S. TALMEY, M.D., Gynecologist to the Metropolitan Hospital and Dispensary, New York. For Physicians and Students of Medicine. With twenty-two drawings in the text. New York: The Stanley Press Corporation.

THIS volume, which is evidently a "labor of love" on the part of the author, is divided into eight parts, entitled respectively: Introductory, Evolution of Sex, Anatomy of the Genitals, Physiology, Pathology, Hygiene, Psychology, and Morality. It contains ninety-seven chapters, some of them less than a page in length, and deals with well nigh everything connected with the emotions of feminine love. There is certainly no lack of books treating of sexual matters, and the present volume is the result of the author's gleanings in this field of literature. In spite of the statement on the title page, we do not expect to see this book among those recommended to medical students in the catalogues of the various medical colleges, nor do we imagine that the professors in those colleges will take this book as the basis of a course of lectures, or that they will begin now "to impart to their pupils all their knowledge about the nature of things concerning Love that they have gathered in their long and extensive experience." We very much question the utility of books of this sort, for they are sure to fall into the hands of those to whom they will be apt to do harm. The well-instructed physician gains all necessary knowledge of sexual matters from purely scientific works.

A MANUAL OF PRESCRIPTION WRITING. With a Full Explanation of the Methods of Correctly Writing Prescriptions, a Table of Doses Expressed in Both the Apothecaries' and Metric System; Rules for Avoiding Incompatibilities and for Combining Medicines. By MATTHEW D. MANN, A.M., M.D., Professor of Obstetrics and Gynecology in the Medical Department of the University of Buffalo, Fellow of the N. Y. Academy of Medicine, of the American Gynecological Society, and Corresponding Fellow of the N. Y. Obstetrical Society. Revised by EDWARD COX MANN, M.D., Lecturer on Obstetrics, Medical Department of the University of Buffalo, Fellow of the Buffalo Academy of Medicine. Sixth Edition, Revised, Enlarged, and Corrected according to the U. S. Pharmacopœia of 1906. New York and London: G. P. Putnam's Sons, 1907.

TO those who need instruction in the matter of prescription writing this book will be serviceable. In this new edition, the chapter on Incompatibilities has been rewritten, and that on Doses has been revised. The volume is of handy size, and contains all that a student will want on the subject with which it deals.

Society Reports.

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

Seventh Triennial Session, Held at Washington, D. C., May 7, 8, and 9, 1907.

DR. REGINALD H. FITZ OF BOSTON, MASS., PRESIDENT, IN THE CHAIR.

(Special Report to the MEDICAL RECORD.)

Tuesday, May 7—First Day.

The Evolution of the Idea of Experiment in Medicine.—Dr. WM. OSLER of Oxford, England, read this paper. He said that the fact that man could interrogate as well as observe nature was a lesson slowly learned in his evolution. Of the two methods by which he could do this, the mathematical and the experimental, both had been equally fruitful; by the one he had gauged the starry heights and harnessed the cosmic forces to his will; by the other he had solved many of the problems of life and lightened many of the burdens of humanity. He traced the beginnings of experimental science from its foundation with the Sumarian race. These old Greeks had anticipations of nearly every modern discovery, and there were details of one fundamental experiment, that of the discovery by Pythagoras of the dependence of the pitch of sound on the length of the vibrating chord. The Greeks, however, did not add to their genius for brilliant generalization and careful observation the capacity to carry out experiments, and neither Plato nor Aristotle understood the value of experiment as an instrument of the progress of knowledge. Hippocrates had appreciated the fact more than any of his contemporaries, but even to him facts as obtained by observation were the beginning and end of the art. The great masters of the Alexandrine school were the first great anatomists, and they had an extraordinary quality of zeal for experimentation which, according to Celsus, led to the vivisection of criminals. Among the Empirics arose the science of toxicology and the study of poisons and their antidotes, and not only animals, but criminals were used to test the effects of poisons and the idea of protection by gradually increasing doses of the poison, and the use of the blood of animals rendered immune were understood. Galen was not a greater observer than Hippocrates, but he stood out in our history as the first physician who had a clear conception of medicine as a science. In brilliant experiments upon the heart and arteries he had almost demonstrated the circulation of the blood, and in his work on the nervous system he had anticipated the discovery of Bell and Marshall Hall, and laid the foundations for our knowledge of the physiology of the brain and spinal cord. In none of the writings of the Arabian school was there to be found any solid contribution to anatomy or physiology. Gradually, however, the paralytic-like torpor passed away, and independent spirits like Paracelsus defied all traditions and threw the doctrines of Galen and Avicena to the winds. Throughout the sixteenth century, however, there had been very little experimental work in medicine. Then came the instruments of precision in medicine with the construction of the thermometer by Sanctorius and the pulsilogum of Galielo. Contemporaneously with Sanctorius, Harvey had demonstrated the circulation of the blood, but neither Sanctorius nor Harvey had had the immediate influence upon their contemporaries which the stimulating character of their work justified. In the latter half of the eighteenth century experimental science received its greatest impetus through the work of Spallanzani, who demonstrated the chemical nature of the digestive process, and John Hunter, who was able to raise pathology into a science. In the beginning of the last century the art of observation had found its fullest development in the hands of the French school, by which the diagnosis of disease was put upon a sound basis, and in the forties Virchow revealed for the first time the true seats of disease. The last half of the century could be called the era of experimental medicine, and the great results had been along three lines—the discovery of the functions of organs, the discovery of the causes of disease, and the discovery of new methods of treatment. A single generation had witnessed a complete readjustment of our outlook on physiology, pathology, and practice, and this had all come from a recognition that experiment is the very basis of science. Only a beginning had been made, however, and there was not a department in practical medicine in which there were not innumerable problems awaiting solution, and what was needed was clinicians who could keep in close touch with physiology, pathology, and chemistry, and who were prepared to transfer to the wards through proper channels the knowledge of the laboratory.

Neurological and Psychiatric Diagnosis.—Dr. LEWELLYS F. BARKER of Baltimore, Md., said that no hard and fast line could be drawn between laboratory and clinical diagnosis; the clinic was the mother of the medical laboratory. The anatomical laboratory dated back three hundred years, but the physiological, pathological, and chemical laboratories were creations of the nineteenth century. The establishment of psychopathic laboratories now promised to be of great significance in the advancement of psychiatric diagnosis. The diagnosis of nervous and mental diseases had made but slow progress until very recent times. The relation of symptoms to lesions in neurology were more difficult to determine because of the difficulties in opening the brain and getting at the seat of the trouble. It was much easier to study alterations in the liver or kidneys than to investigate the lesions of the central nervous system, and yet, as had been said, a pin prick in such a part might cause more damage to the general system than the passage of a crowbar through another. Slow but sure progress, however, had been made by the study of autopsies. Helmholz's invention of the ophthalmoscope had done much to advance the science of neurology, and every neurologist now made use of it. The tendency of modern psychology was to become more and more objective and in this way only was it possible to obtain scientific results. The certainty with which a diagnosis in dementia paralytica could now be made was one of the great advances in psychiatry. Dr. Barker thought that a great impetus would be given to this work if psychiatric clinics could be established in connection with every hospital and medical school in this country and he expressed the hope that that would soon be done.

On Chemical and Biological Diagnosis.—Dr. ALFRED STENGLE of Philadelphia had been led to the conclusion that the work of the laboratory man, whether in chemistry or biology, must be constantly checked by the equally important work of the clinician, just as the work of the clinician requires the check of the laboratory worker. His results might be far more erroneous than those of the clinician, but they might be able to advance the science in a way that would never be possible by mere clinical observation. The introduction of chemistry into medicine had begun with the discovery of oxygen, when the possibility of estimating the oxidation going on in the living body was shown. It had been thought then that this would throw a great deal of light upon diseased processes, but so far as diagnosis was concerned the most important thing we had learned was that in diseases where oxidation is supposed to be reduced a reduced oxidation doesn't really exist, as in anemia. It had been thought that the amount of oxidation might be obtained by the studies of urea elimination, but the estimates of urea, without taking into consideration the question of absorption and the intake of food, were absolutely worthless. So far as the total nitrogen was concerned the same thing could be said. As to the production of uric acid and its estimation, fanciful theories of uric acid diathesis had been aban-

doned. As to the carbohydrate metabolism the presence of sugar in the urine was known to be an abnormal condition and when combined with certain clinical symptoms constituted the disease of diabetes. The most important principle that physiological chemists discovered, perhaps, was that the defence of the body against chemical poisons was due to a pairing with other substances in the body, as of one of the acids with an alkali; that urea and bile salts combined with other substances for their elimination. This theory of pairing had led to the discovery of the only genuine autointoxication of which we had any accurate knowledge, that of acid intoxication which occurred in a variety of conditions. In diseases of the stomach a great deal had been expected from investigations of the gastric juice, but the quantitative estimates of the stomach contents had not proven as valuable as studies of the motility of that organ. Conrad's method for diagnosis of typhoid the writer considered an improvement over the Widal reaction. As to tuberculin he thought the views of Dr. Trudeau deserved more general acceptance, namely, that if carefully used small amounts of tuberculin were safe and the diagnosis was greatly facilitated by its use. With regard to the opsonic index there could hardly be a positive expression of opinion as yet, and certainly the difficulty of making the examinations rendered the test of doubtful value to practitioners.

Physical Diagnosis.—Dr. Richard C. Cabot of Boston hoped that this Congress and the year 1907 would mark and end of the false and harmful distinction between laboratory and clinical methods of diagnosis, for the distinction could not be defined and did not, in fact, exist, although we attempted sometimes (and most disastrously) to approximate to it. There should be no diagnoses made merely in the laboratory and none merely at the bedside. The degree of exactness in any technical procedure depended wholly on the end to be secured. We might have too much exactness as well as too little. But, we could not have too much clearness in the expression of our results. Modern physical diagnosis showed (among others) two dominant tendencies: (a) to seek for and prize the most direct methods of examination; (b) to lay stress upon the present functional capacity of an organ rather than upon the present appearance of anatomical lesions. The writer believed that the oldest methods—inspection and palpation—were still the best. Among recent additions to our technical resources three could be mentioned as likely to stand the test of time. These were: (a) *x*-ray examination; (b) blood-pressure measurements; (c) palpation of the abdomen beneath the surface of the warm bath In the examination of sputa we had progressed from the complex to the simple. Reduced to its essentials, sputum work to-day meant a good look at the sputum in bulk, the judicious use of one's nose, and the search for tubercle bacilli. Curschmann's spirals, Charcot-Leyden crystals, fibrinous casts, influenza bacilli yielded no clues for diagnosis, prognosis, or treatment.

The Borderland of Medicine and Surgery. President's Address.—Dr. Reginald H. Fitz, Boston, delivered this address. He said that on the front of the building erected for the Harvard Medical School in 1883 were inscribed the names, Hippocrates, Celsus, Galen, Vesalius, Paré, Haller, Harvey, Sydenham, Hunter, Bichat. Of all the names in medical history these had been deemed the most worthy of such distinction, as each of these men represented a new epoch, and the influence of each in his turn had been of undying influence in the progress of medicine from the age of Pericles to the present day. Medicine had become divided and subdivided into its various specialties and advance had been made now in one direction, then in the other, but the unity of medicine had ever remained paramount and whatever had benefited a part had always proved an advantage to the whole. Dissensions had lessened, distinctions had become recognized, and a borderline had been traced, shadowy to be sure, but ever changeable and surrounding a territory open to each and productive for all. The speaker called attention to some of the landmarks in this borderland of medicine and paid tribute to those who had been instrumental in establishing them and indicated some of the means by which this region should continue productive. He traced the advance of medicine from the Hippocratic period, four or five centuries before Christ, when but one healing art was recognized, that of medicine, when the physician was conversant with disease only and there was no surgeon, through the Alexandrine period when the separation of surgery from medicine began, through the Roman period when Celsus recorded the state of medical knowledge at and before his time, during the period when Galen who lived a century after Celsus, when the distinction between medicine and surgery became well established, through the period when the Arabs preserved and maintained the best of Greek medicine, the further developmnt of medicine and surgery as fostered in the schools of Salernum and Montpelier and later by the Universities of Italy and France, which later gave way to the Universities at Naples, Bologna, and Padua, down to the present time, when surgery had become a science. To John Hunter, anatomist, physiologist, pathologist, and surgeon, was due, more than to any other man, the scientific foundation of surgery as a science. The effect of Hunter's work was greatly enhanced by that of Bichat, equally distinguished for breadth of mind, intensity of application and genius for generalization. After the construction of the microscope and the progress made in chemistry, the recognition of pathological histology and of cellular pathology, scientific medicine, and scientific surgery became definitely established and the practitioners began to appreciate the value of the broader training. The center of scientific thought became transferred to Germany and became lustrous chiefly through the teachings of Virchow, pupil of Johannes Muller and of Schonlein. The discoveries in medicine during the latter half of the nineteenth century had added more to the welfare of man, as manifested by relief from suffering and disease, than the sum of all known efforts in this direction since the origin of man. Common to medicine and surgery they had been alike beneficial to each and had resulted in a redistribution of the borderland of medicine and surgery, adding more and more to the domain of surgery, while opening fresh fields to the labors of physicians. With due appreciation of the great benefits that had arisen from the surgical invasion of the borderland, there still existed sufficient reason to progress slowly and cautiously, as operative success was not necessarily a justification for operation, as had been recognized by those who were brought in contact with the failures. The successful invasion of the borderland by the surgeon was due mainly to the fact that surgery had become science. Thorough training in the laboratories was the best preparation for contact with disease and the more thorough the preparation of the physician and surgeon the more skillful and beneficent would be their art and the more exact and productive their science.

Wednesday, May 8—Second Day.

The subject for discussion was "The Comparative Value of the Medical and Surgical Treatment of the Immediate and Remote Results of Ulcer of the Stomach."

Indications for, Methods of, and Results to be Expected in the Medicinal Treatment of Ulcer of the Stomach.—Dr. John H. Musser of Philadelphia opened the discussion of this subject, and, after reviewing voluminous statistics, concluded that gastric ulcer is a medical disease. Gastric ulcer with complications and sequelæ is sometimes a surgical disease, and if perforation occurs it becomes a surgical affection at once. If hemorrhage occurs acutely it is rarely a surgical affection; if repeated and chronic, it is surgical. If the ulcer is productive of perversion of secretory function alone, it remains a medical

affection. Inasmuch as hyperchlorhydria is in part a neurosis, the secretory function can be balanced chiefly by medical, dietetic, and hygienic measures. Even if pyloric spasm attends the hypersecretion and hyperacidity, it does not necessarily take the case beyond medical care. It is wrong to submit such a class of cases to operation, unless motor disturbances come to the foreground. If the symptoms and physical signs of retention from obstruction, dilatation, hour-glass contraction, or adhesions supervene and persist, the case is a surgical one. If the symptoms of gastric ulcer become continuous in spite of medical treatment, and incapacitate or threaten life, if hemorrhage recurs and secondary anemia arises, it is a surgical disease. Such cases are always attended by organic sequelæ. The extraordinary frequency of chronic gastric ulcer with sequelæ requiring operation at the present day is due to neglect of the treatment of an ulcer in its incipiency. Statistics show that most cases are operated on between the thirtieth and fortieth year, and have an ulcer history of five to ten years' duration. The evidence is not sufficient to show that gastric ulcer is a forerunner of gastric cancer. After the surgical procedures of necessity are carried out, the case must be treated medically. Medical treatment must be continued over a period of four months at least; hygienic and dietetic over a period of years; the best permanent relief and the most complete restoration to health occurs in those cases which recover after perforation of the gastric ulcer; an operation which if possible could approach this accident in an anatomical result would be the best.

Dr. Charles G. Stockton, Buffalo, New York, said that Dr. Musser had assembled the evidence that recent experience had made possible in the medical treatment of peptic ulcer, and pointed out what advance had been made, and, to decide in view of all these facts the most judicious course to pursue, without attempting to press overmuch the importance of any particular method of treatment, was a task. Did we permit ourselves to take a brief in championing some method with the zeal that success in a comparatively small group of cases sometimes suggests, we would undoubtedly fail. It was very important at this period not to array against each other the comparative advantages of medical and surgical practices. Rather there should be made the deliberate effort so to view the matter that we might concur in deciding upon the place of each in the treatment of this disease. We should attempt to exclude certain cases that closely resemble in symptomatology peptic ulcer, but in which, despite the occurrence of pain, tenderness, spasm, vomiting, and hemorrhage, no ulcer actually exists. He denied that it was always true, as had been asserted in some quarters, that these cases do in fact suffer from undiscovered ulcer or fissure, because oozing of blood might be seen through the turgid, deeply-congested mucosa, that showed no lesion even under the magnifying glass, and because superficial erosions or fissures in an otherwise healthy stomach are rapidly cured by nature, and are practically without symptoms. Those ulcerated processes dependent upon special infections, like syphilis, tuberculosis, and pyemia, should be excluded from the consideration. There remained two distinct divisions of peptic ulcer; first, the more frequent type, the acute, which occurs in younger patients and appears often in chlorotic young women, and, second, the type more commonly developing in older patients, those past middle life. The prevention of gastric ulcer could be summarized thus: maintain a calm nervous system in a well-conditioned body; the medical treatment; to make a positive diagnosis begin treatment early, and carry out with painstaking attention the details for a long time; general rest; in some cases discreet feeding, in others periodical starvation, depending for support upon frequent small enemata of normal salt solution. For the control of hemorrhage, in addition to rest, local treatment through the stomach tube, using ice water, adrenalin solution, and gelatin water. In irritating hyperacidity one should use local general sedatives and antacids. To relieve hypertension and spasm of the stomach, in addition to suitable drugs, the external applications of Von Leube. Treatment should be continued long after apparent cure and the stools studied for occult blood. The indications for surgery were for the relief of results of gastric ulcer rather than for the cure of the disease itself.

The Contribution of Surgery to a Better Understanding of Gastric and Duodenal Ulcer.—Dr. William J. Mayo, Rochester, Minn., divided ulcers of the stomach or duodenum into two classes, indurated or nonindurated. The indurated ulcer involves all of the coats of the stomach or intestine, and its existence may be demonstrated from the exterior of the organ. All of the notable contributions of surgery to our knowledge of ulcer concerned this group. Surgical investigation had shown, first, that ulcer of the duodenum in the upper inch and a half is as common as ulcer in the whole of the stomach. Second, that the majority of ulcers, called pyloric, have their origin in the duodenum. Third, that the male sex is more frequently afflicted with ulcer of the stomach and duodenum (62 males to 38 females) by reason of the fact that 77 per cent. of duodenal ulcers are in the male, true gastric ulcer being about even in the two sexes, 52 males to 48 females. Fourth, that cancer frequently has its origin in ulcers. In 54 per cent. of 69 cases of cancer of the stomach submitted to resection by Dr. Chas. H. Mayo and the writer in 1905-06, cancer could be demonstrated to have had its origin in ulcer. Nonindurated mucous ulcer, also described as clinical or medical ulcer, gives no evidence from the exterior of the stomach or duodenum of its existence, and unless the interior be successfully explored the diagnosis remains in doubt. Nearly all the failures in the surgery of ulcers concerned this group. The existence of acute nonindurated mucous ulcer was shown by operations for acute perforations, hemorrhage, and post-mortem investigations of deaths from these causes. Chronic nonindurated mucous ulcer was certainly very rare. The large majority of cases so diagnosed were in reality nonsurgical conditions, such as pyloric spasm, atonic dilatation, gastroptosis, and the gastric neuroses. If a diagnosticated chronic nonindurated mucous ulcer (clinical ulcer) cannot be demonstrated at the operating table, it probably does not exist, and operation should not be done on an improved hypothesis, unless complications such as hemorrhage, perforation, or obstruction coexist.

Dr. John C. Munro, Boston, had made an analysis of 150 cases. Of these 87 showed gross ulcer of the stomach or duodenum; 16 belonged to the class of so-called medical ulcer, where no gross ulcer could be found at operation; 25 showed well-marked adhesions, without evidence of ulcer; 15 were the so-called neuroses, and 9 classed as ptosis, spasm of the pylorus, etc. As to the question of immediate gastroenterostomy in perforation, he believed the anastomosis shortened convalescence and tended to obviate the necessity of secondary operations. The simpler the technique and the nearer we followed anatomical lines the better the result. The different methods of operation were gone over in detail. Excision of the ulcer area, which is also the cancer area, he considered the ideal operation after middle life. The decision upon the type of operation depended upon the individual case and the experience of the operator. The simplicity and cleanliness of the clamp and suture operation spoke highly in its favor, and he thought was to be preferred to any other. When relief was obtained in these cases it excelled that in almost any other class of diseases, besides relieving the chances of engrafted malignancy.

Dr. A. Jacobi, New York, in discussing the subject, said that ulcers of the stomach, both acute and chronic, were frequent at every age. There were those whose experience permitted them to say that from two to five per cent. of the population suffer from it. Brinton collected 226 cases, of whom 2 were under 10 years of age; 18, from 10 to 20; 43, from 20 to 30; 38, from 30 to 40; 38, from 40 to 50;

32, from 50 to 60; and 32, from 60 to 70. Similar results had been obtained by Cruveilheir and by Rokitansky. A late case had been published by Immerwohl, the patient being four years old, with a chronic ulcer and nephritis, dying of uremia. Ulcer of the stomach, in its most dangerous form, was not infrequent in the infant. Between the seventh and thirteenth year was not at all rare. Most ulcers were found on the posterior wall near or in the small curvature; the next locality of predilection being the neighborhood of the pylorus, while some were found in the cardia or in the fundus, in the anterior wall and the large curvature. The size might be no larger than the head of a pin, detected with difficulty at autopsy, while they might be the size of a hand. As to the occurrence of hemorrhage his own observation, extending over a period of fifty-four years, of private and hospital practice, coincided with that of Leube, that it occurred in less than one per cent. His experience as to perforations also coincided with that of Leube that they occurred in about one to two per cent. As to the mortality reports the vast differences ranging from 2.4 per cent. to 50 per cent., proved for the thousandth time that statistics may be the most deceptive and most irrational method of dealing with any clinical question. The experience of the general practitioner in a large practice among the poor or among the rich, among men or among women, the general physician with a family practice only or an office practice preeminently, the consultant who is called in to see bad cases only, the stomach specialist, the surgeon in general practice, the hospital physician in whose wards bad cases only take refuge, the hospital surgeon who never sees anything but hemorrhages and perforations, gives a variety of observers but a variety of cases. Exclusive hospital physicians and surgeons have little experience with the average ulcer of the stomach; theirs being only an experience with bad or fatal cases. Their statistics referred to hemorrhages and perforations, not to chronic ulcer of the stomach. The main symptoms of gastric ulcer were given as pain, hyperacidity, and sometimes hemorrhage. The presence of ulcer required constant alkalinization of the stomach, the administration of an alkali at long intervals being insufficient. He gave an alkali before every meal and at intervals of two hours for months, and preferred those which contained no carbonic acid, which inflated the stomach. The best was magnesia, magnesium oxide, three to four grams a day. Bismuth subcarbonate, not subnitrate on account of its gritty condition, might be safely added. The speaker felt positive from what he knew of the frequency of gastric ulcer in general practice and of the long time it takes negligent or indigent patients to nurse their illness up into the stage of hemorrhage or perforation that it was often cured and prevented from the necessity of getting into the medical or surgical hospital ward. Conservative surgeons admitted that seventy-five per cent. of gastric ulcers were cured by internal treatment. After the operator had performed his duty the case became again that of the practitioner and there might be an organ of doubtful utility, for the creation of a funnel was not the restoration of a normal stomach.

Dr. E. G. Janeway, New York, believed that the medical men and the surgeons were now pretty well agreed on this subject; certainly they were in entire accord as to perforation; where there was perforation operation was indicated and indicated at once if the best results were to be expected. The same was true of stenoses and obstruction of the pylorus with cicatrices. He did not feel that lavage was advisable in these cases and referred to two instances where death had been produced by its employment. He had the same objection to the use of subnitrate of bismuth that Dr. Jacobi had mentioned; it could be seen under the microscope to consist of crystalline flakes with sharp edges, and why it had remained so long a favorite remedy he could not understand; he had had one case in which the sharp flakes were found in the passages. He preferred the subcarbonate or subgallate. He did not advocate the use of subnitrate of silver in these cases, as there was no certainty of touching the ulcer with it. He advocated Trueau's method of requiring the treatment to extend over a period of two years. The patient should be put on his guard and told that he has a chronic disease for which the treatment must be kept up for a long time.

At the conclusion of the meeting the Secretary, Dr. Wm. H. Carmalt, was presented with a silver loving cup by the presidents of the Congress and presidents of its constituent associations in appreciation of his faithful and untiring efforts for the success of the organization.

ASSOCIATION OF AMERICAN PHYSICIANS

Twenty-second Annual Meeting, Held in Washington, D. C., May 7, 8, and 9, 1907, in Conjunction with the Congress of American Physicians and Surgeons.

FRANCIS P. KINNICUTT, M.D., NEW YORK, PRESIDENT, IN THE CHAIR.

(Special Report to the MEDICAL RECORD.)

Tuesday, May 7—First Day.

The President's Message.—Dr. FRANCIS P. KINNICUTT of New York City, in formally opening the meeting, emphasized the mutual dependence of the science and practice of medicine, as would be clearly illustrated by the scientific program to be presented to the association at this time. He briefly reviewed the professional careers of Dr. James Stewart of Montreal, Dr. Isaac Edward Atkinson of Baltimore, and Dr. Thomas Lattimer of Baltimore, all deceased since the last meeting of the association.

The Connection of the Occipital Lobes and the Present Status of the Cerebral Visual Functions.—Dr. ADOLF MEYER of New York City presented this paper, which was illustrated by a number of lantern slides. The following points were developed: (1) Isolation of the geniculocalcarine trace (two cases). (2) Subdivision of sagittal marrows and their course. Marking of the calcarine area. (3) Degeneration of the occipital efferent path and the geniculocalcarine tract, following degeneration of the calcarine cortex. (4) Marchi-degenerations from a small wound of the postparietal cortex, involving the optic radiations: (a) Afferent character of the external sagittal marrow; (b) efferent character of the internal sagittal marrow (contributing to the lateral part of the crus); (c) subcortical (external sagittal) fibers towards the motor area; (d) no fibers to the frontal lobe. (5) Anatomical data for clinical correlations.

Dr. L. F. BARKER of Baltimore emphasized the importance for diagnostic purposes of such studies as Dr. Meyer had outlined. He believed that it was only through such careful study that any definite knowledge could be obtained concerning the cerebral visual functions.

Certain Features of the "Nervous Breakdown" with Special Reference to Treatment.—Dr. JAMES J. PUTNAM of Boston, Mass., in this paper, emphasized the view that the acute "nervous breakdown" really typified processes which were characteristic of more chronic neurasthenic conditions, but which afforded especially good chances for observation, because the illness ran its course, practically, under the physician's eye. The so-called "traumatic neurosis" was perhaps the most striking example of this acute breakdown, being characterized by its period of predisposition, followed by periods of nervous shock, of apparent absence of symptoms, of gradually increasing illness, of an apparently stationary stage, of convalescence and recovery. Similar processes were frequently observed as a result of nontraumatic shock, of strains during school and college life, and many analogous influences, while diminutive periods of like type were fre-

quently met with as intercurrent events in the course of chronic illnesses. The controlling influence in the causation of these states, and the controlling means of treatment, was the mental state of the patient. To the consideration of this factor the paper was chiefly devoted. The means of increasing the patient's available stock of mental energy were among the principal therapeutic points considered. In this connection Dr. Putnam emphasized the importance of the different methods of reeducation, as developed by S. Weir Mitchell and others. While philosophy and ethics could not be presented to the patient in a technical way, yet if physicians were more trained in this department of learning, their efforts would be more effectual. A strong plea was made for such training. The relation between the mental processes and the physiological functions having to do with nutrition, etc., was also emphasized.

Dr. John K. Mitchell of Philadelphia asked for enlightenment in the management of the acute stage of "nervous breakdown."

Dr. Adolf Meyer of New York was of the opinion that the abstract statement that physicians should teach philosophy and ethics to patients would lead to a misconception on the part of many physicians of the whole movement. As modern psychology had arisen largely out of the experience of physicians, so the philosophy and ethics of the future would find a large source of facts in the experience of physicians. Taken from this point of view—not of abstract ethics, but the formation of habits, the arranging of definite régimes of habits and reaction types—the suggestion was important in the treatment of neurasthenics and other mental disturbances.

Dr. Charles L. Dana of New York City thought that in the majority of instances of "nervous breakdown" if the patient were put under ordinary common-sense environments recovery would take place within six months or a year. Many cases of neurasthenia, however, were not merely nervous breakdowns, but were psychoses. A certain percentage of persons were of a nervous disposition, and in the event of a breakdown such an individual would have a psychosis; this, however, would run its course. The majority of neurasthenic cases, put under proper mental, moral, and physical surroundings, would recover.

Dr. A. Jacobi of New York, speaking as a physician and not a neurologist, would examine such patients from an additional point of view. The cases he had seen had, almost without exception, suffered from mild cardiac changes. Upon exertion on the part of the patient a feeble murmur could invariably be heard, and this physical change, whether of the nerves or muscle of the heart, should be treated as well as the psychical condition.

Dr. S. Weir Mitchell of Philadelphia called attention to the fact that a nervous breakdown might be brought on by mental conditions and emotional disturbances, and sometimes by a physical breakdown.

Dr. Putnam, in closing the discussion, agreed with all the speakers. Replying to Dr. John Mitchell's question concerning the treatment in the acute stage, in traumatic cases he had found that rest and encouragement had considerable effect, though sometimes little could be accomplished thereby. He agreed with Dr. Meyer that the whole matter should be put on the simplest and most matter-of-fact basis possible. In a measure he agreed with Dr. Dana's suggestion that these accidents and strains initiate a psychosis which must run its course. This psychosis, as Dr. Jacobi suggested, was not a pure psychosis, but had its physical side.

The Clinical Study of Aphasia.—Dr. Charles L. Dana of New York City presented, in this paper, the analysis of a series of cases of aphasia, clinically studied, with the object of securing a grouping of the aphasias as they are seen at the bedside, with a description, so that such groups might be recognized by the physician and taught to the student. The views of Professor Pierre Marie were discussed in the paper. Dr. Dana presented a method of diagrammatically representing the type of aphasia upon certain charts devised by himself. He thought it would be best to teach students to make the classification of aphasia on an anatomical basis, to find out the kind of aphasia the patient had and then locate it, in the temporal, frontal, parietal, or occipital lobe, as the case might be.

Dr. W. M. Thompson of New York City, from his own clinical experience, was not inclined to attach much importance to the cases of aphasia detailed by Marie in which it was claimed that each one was accompanied with motor symptoms, showing that the lesion had extended to the motor region.

Dr. James J. Putnam of Boston was glad to hear Dr. Dana put himself on record as recognizing the various types of aphasia.

Dr. Morton Prince of Boston did not accept Marie's view that all aphasias are intellectual aphasias expressing themselves in this or that direction.

Dr. Dana, in closing the discussion, said that he had not brought out Marie's point of view, although it was difficult to treat the subject without reference to it. Marie had not proven that the frontal lobe is not a language center; there was much absolute evidence that it was, clinical and pathological reports leaving little doubt on the subject. Aphasia was not sensory, nor was it motor, but sensorymotor.

The Presence of Inflammatory Masses in the Abdomen Simulating Malignant Growths.—Dr. E. G. Janeway of New York City presented this paper, citing in detail a number of cases in which masses, discovered by palpation and ordinary examination, or by these and laparotomy, were considered malignant, but disappeared later. Of the cases mentioned two occurred in connection with ulcer of the stomach, the others in different places in the abdomen. He did not advocate exploratory laparotomy in these cases, but thought it better to wait. Many of the cases of tumors reported as having disappeared under treatment with *x*-ray and other measures he believed to owe their disappearance to time.

Dr. William Osler of Oxford, England, said these cases might be divided into the following groups: those associated with the gall-bladder, those associated with the stomach, the appendicular cases, and those in which the trouble is in the cecum. He had had his attention called to cases in which there was a mass in the left iliac fossa. This might be due to thickened glandulæ epiploicæ. This was found to be the case in two instances. In another case there was thickening due to perforation by a foreign body. He agreed with Dr. Janeway's attitude concerning surgery, and yet in many instances operation was very satisfactory, being followed by disappearance of the tumor.

Dr. Charles Bond of Richmond, Indiana, cited a case in which it would not have been well if the patient had fallen into the surgeon's hands. The tumor disappeared in the course of two or three years.

The Etiology of Acute Pancreatitis.—Dr. H. U. Williams of Buffalo presented this paper, which detailed experimental work done by Dr. Williams and Dr. F. C. Busch, also of Buffalo. The part played by gallstones in the production of acute pancreatitis was considered, and cases of this kind analyzed.

Dr. Eugene L. Opie of New York City, in discussing this paper, said he was surprised to find that the number of cases of acute pancreatitis in connection with gallstones, as given in the extensive literature collected by Dr. Williams, was so small. This was probably due, as suggested, to the fact that the bile ducts were often neglected in the examination.

The Calcium, Magnesium, Phosphorus, and Nitrogen Balances in a Case of So-called Phosphatic Diabetes.—Dr. L. F. Barker of Baltimore, Md., read this paper, which was prepared jointly with Dr. C. Voegtlin of Baltimore. The paper included the results of a metabolic study in a

case of so-called phosphatic diabetes. A woman who for years had suffered from dry skin, cracking of the heels, and nervousness, and who had had constantly urine of high specific gravity and high acidity, was placed upon Folin standard diet, and the calcium, magnesium, nitrogen, and phosphorus balances studied. The metabolism was abnormal in that the urine on a standard diet presented a very high organic acidity not due to uric acid, to phosphates, or to lactic acid.

Dr. WILLIAM OSLER, under whose care the patient had come from time to time, said that the chief point of interest was the fact that the symptoms would lead anyone to the diagnosis of diabetes, and yet repeated examination failed to discover any trace of sugar. He had always regarded it as a case of prediabetic condition, and expected each time the patient presented herself to find sugar in the urine.

Dr. A. E. TAYLOR of Berkeley, California, detailed experiments which he had carried out upon himself, with a calcium free diet. The symptoms were those of lassitude up to the sixth day, when there was marked muscular twitching, loss of sleep, and extreme irritability. Realizing at this stage of the experiment that the danger point was being reached, he returned to the normal diet, the equilibrium returning immediately.

Dr. BARKER, in closing the discussion, said the salts were just as important in the food as were the other elements. He emphasized the importance of maintaining the balance of the inorganic substances. Working along this line, it might be found that neuroses and psychoses had an organic basis.

The Relations Between Diabetes and Pregnancy.—Dr. AUGUSTUS A. ESHNER of Philadelphia maintained, in this paper, that diabetes was uncommon during pregnancy in proportion as it was uncommon during the child bearing period. Exceptionally it had recurred during successive pregnancies. Pregnancy rarely occurred in diabetics, partly because diabetes in women is most common after the menopause, partly because of the debilitated general state of the diabetic patient, and partly because of the functional derangement and the structural alteration of the generative organs. The complication of the one condition with the other usually increased the gravity of both. Often the fetus died *in utero*, or premature labor set in, the fetus dying at birth or shortly thereafter. The liquor amnii had been found increased, and, in some instances, also to contain sugar. The mother sometimes died of the disease shortly after labor. In Dr. Eshner's case of diabetes the sugar disappeared from the urine with the inception of pregnancy, remaining absent until after the birth of a macerated fetus at term and reappearing shortly afterward.

AMERICAN GYNECOLOGICAL SOCIETY

Thirty-second Annual Meeting, Held at Washington, D. C., May 7, 8, and 9, 1907, in Conjunction with the Congress of American Physicians and Surgeons.

DR. CLEMENT CLEVELAND OF NEW YORK, PRESIDENT, IN THE CHAIR.

Tuesday, May 7—First Day.

Metastatic Carcinoma of the Tube and Ovary in Cancer of the Cervix Uteri.—Dr. FRED J. TAUSSIG of St. Louis, Mo., read a paper on this subject, in which he concluded that mild, chronic inflammatory conditions of the tube and ovary were frequently met with in cancer of the cervix. Whether this was merely coincidence or not he would be unwilling to say. On the other hand, cancerous metastases in these organs were extremely rare in cervical cancer. In fact, he could find no record of such metastasis in an operable case. In carcinoma of the body, however, they were not infrequently seen in tube or ovary, or both. Hence it would seem logical to advise the removal of both tubes and ovaries in every case of cancer of the body. If, however, the patient was still five to ten years from the time of the menopause, and the site of the cancer be in the cervix, the saving of one ovary would be attended with practically no risk to the patient and might relieve her of the disagreeable symptoms of the premature menopause. Since this could be done without interfering with the complete removal of the lymphatics directly tributary to the cervix, he believed it logical to leave one ovary, or a portion of one ovary, in every operation for cervical cancer in a woman under forty years of age.

Dr. J. WESLEY BOVEE of Washington, D. C., said metastases in cancer of the uterus were by no means common, and that as the disease spread metastases occurred. This emphasized the fact that in the cases brought to the attention of the gynecologist he was helpless in the treatment of cancer of the uterus; that in the cases in which the conditions would ordinarily offer great hope of success we would find that metastases occurred in those structures which we would not remove, the result being that cancer recurred or continued unsuspected. At best the treatment of cancer of the uterus was not hopeful, notwithstanding the claims of radiographers and the demonstrators of radium, etc., and those who did the most radical surgical operations. He was not prepared in the present light of surgery of cancer of the uterus to accept the suggestion of the essayist, that it is safe to leave a portion or even one ovary in extirpating cancer of the uterus. His own conviction was that the operation should be as radical as it could be consistent with saving the life of the patient.

Dr. LAPTHORN SMITH of Montreal, reported a case of cancer of the cervix in which operation was done early by another surgeon, with every possibility of a complete recovery of the patient and freedom from recurrence; yet this woman came to him a year later with no sign of recurrence in the vagina, but with two distinct masses in the ovaries which could be readily felt. He considered it too late to do anything in an operative way. This case made such an impression on him that ever since, when doing vaginal hysterectomy, he always removed the tubes and ovaries. He did not think it was safe to leave an ovary or a piece of an ovary when there was such a tremendous risk of recurrence.

Dr. REUBEN PETERSON of Ann Arbor, Mich., desired to place himself on record as voicing the sentiment of Dr. Bovee against the leaving of one ovary, or part of an ovary, in the operation for cancer of the uterus. This was a step backwards, and was not in accordance with the progress that had been made in the last ten years in the treatment of cancer of the uterus. He was not convinced that the leaving in of one ovary, after the removal of the uterus, helped the patient, so far as the menopausal changes were concerned. He had been unable to see much, if any, difference where an ovary had been left in, and where it had been removed, after the removal of the uterus for cancer.

Dr. WALTER M. CHIPMAN of Montreal doubted whether it was a wise thing to leave even one ovary, or even a part of one, after the removal of the uterus for cancer, no matter where the cancer was situated. While it was true that the ovary was not in the direct path of the lymphatic distribution of the pelvis, yet so great and so rich was the anastomosis that he thought the leaving of ovaries must always be a risky procedure.

Dr. TAUSSIG, in closing the discussion, said he anticipated that most men would hardly agree with him as to the advisability of leaving a portion of an ovary in the class of cases under discussion; but he believed, however, from the statistics that the procedure was not at all unsafe, and it seemed to him that it was just as logical to advise the removal of the appendix as to advise the removal of

the other ovary. The appendix was a useless organ; the ovary—at least, in the opinion of some—helped to make the menopausal disturbances less severe in women under forty years of age, if left.

A New Method of Version.—Dr. A. F. A. King of Washington, D. C., spoke of the correction of transverse presentations by the hitherto unrecognized factor of thigh-pressure upon the abdomen, induced either (1) by posture, or (2) by manipulating the lower limbs. The former, he said, was Nature's method of preventing and correcting cross-presentations; and in primitive races was daily exercised by the squatting posture during defecation, etc. Squatting was not a symmetrical proceeding; the two thighs did not press equally. One foot was flat upon the ground and in advance, the other in the rear, rested only on its toes. The thigh of the front foot would press high up upon the breech end of the fetus; the thigh of the rear foot would press low down upon the head, forcing it from the iliac fossa into the pelvic brim, as was illustrated by diagrams.

The Superiority of Primary Over Secondary Cesarean Section; Feasibility and Advantages of a Predetermination of the Method of Delivery.—Dr. Edward Reynolds of Boston spoke of primary operations being determined upon in advance of labor and performed at an elected date, or with the advent of the first pains. Secondary operations might be performed as soon as a test in labor had shown that the natural powers were likely to fail and before serious exhaustion set in. Late operations were considered in the light of a last resort. Late sections were already discredited, while secondary sections were still the most frequent class. He gave the statistics of primary, secondary and late sections of the last ten years. Primary section was a very safe operation, while secondary section was only moderately safe. Late section was attended with a high mortality. In general, the mortality was roughly proportionate to the amount of labor endured before operation. Decision before labor was a matter of great moment. The doubtful cases were constantly narrowing and should be done away with. Accurate prediction of expected difficulty required: estimation of the shape and relation of the pelvis (measurements alone were entirely unreliable); of the probable muscular character of labor; of the size and ossification of the head. Methods of estimation of the maternal obstacles required knowledge of the maternal powers (these could be foretold with considerable accuracy) and of the mechanical character of the head. He emphasized the value and importance of obtaining a previous history in multiparæ. He submitted the following classification: A, undoubtedly cesarean section cases; B, cases clearly capable of delivery without the cesarean; C, doubtful cases.

As to the treatment, in class A he would resort to primary section; in class B labor and the intrapelvic operations. In class C a final examination under ether at the date of election, the method finally decided on, and decision adhered to. The predetermination of methods was work for experts only. Lastly, he pointed out that a more friendly relation between the specialist and the general practitioner was desirable.

Pubiotomy.—Dr. Henry D. Fry of Washington, D. C., read a paper on this subject. Pubiotomy was a satisfactory operation, so far as the operation itself went, for enlarging the pelvic girdle in moderate degrees of pelvic contraction. It was easy to perform and could be employed in simple flat pelves with a conjugata vera of 7 or 7½ cm. Separation of the severed bone for 4 or 5 cm. was usually sufficient to enable easy extraction with forceps. The principal objection to the operation was the difficulty encountered in the after-treatment. These difficulties were little, if any, less than those which brought symphyseotomy into disrepute. The pelvis must be immobilized and the patient kept in the dorsal position several weeks. Maternity institutions could overcome the objection to a large degree by the use of a special bed, as the hammock suspension bed described by Ayres. Williams used the Bradford frame after two of his operations. Jewett employed an ordinary hospital stretcher, "the poles of which were lashed to the top rails of an iron bedstead. A trapdoor was provided for the dejecta." Montgomery recommends a pelvic sling suspended from the ceiling and attached to a compound pulley. Ordinarily, after pubiotomy and symphyseotomy, the evacuations of the bladder and bowels were attended with discomfort, and it was a hard task for the nurse to keep the parts clean, which was the more important after secondary operations where the patient was already septic and the soft parts contused and lacerated. In consequence, therefore, of the unsatisfactory convalescence after pubiotomy, the operation would obtain in this country a limited field of usefulness as an elective operation. Cesarean section offered a substitute free from this objection, and its indications would be extended to embrace these cases of minor degrees of pelvic contraction. With a head movable above the inlet, and one which would not descend by suprapubic pressure, that operation should be performed primarily. When the head was moulded and engaged, forceps might be tried tentatively before resorting to section. The indications for pubiotomy might be stated as follows: A living child and some contraindication to cesarean section. The usual conditions presented were: a moderate degree of pelvic contraction, which had been unrecognized generally, ineffectual efforts employed to deliver with high forceps, the woman exhausted, and infection probably started. If the child were dead, craniotomy; if alive, pubiotomy, in spite of the objections raised against it. It was better to have a live woman at the end of a tedious convalescence than a dead one after a "successful" operation.

Induced Labor and Delivery by Abdominal Section.—Dr. Edward P. Davis of Philadelphia said that among obstetric operations there was none which in selected cases gave better results than the induction of labor. This was especially true in disproportion between mother and child, whether caused by pelvic contraction, excessive fatal size, or prolonged pregnancy. Private patients were especially benefited by this operation, as they usually came early under the care of the obstetrician and gave him a better opportunity to study their cases than did hospital patients. Private patients who had passed through a disastrous first confinement were often safely delivered in subsequent labor by the induction of labor. Experience, however, and the study of statistics showed that induction of labor was not without serious disadvantages; it was a process uncertain in duration, often exposing the patient to considerable loss of rest and to prolonged suffering. Labor was rarely terminated without some active interference, and this was most often to be accomplished through a cervix poorly prepared for dilatation. Some of the methods employed to terminate induced labor produced unfavorable presentations and positions of the fetus, increasing the risks to mother and child. While it was possible, considering the interests of the mother first, to have a low mortality and morbidity rate for her, the best results so far published gave a very considerable mortality and morbidity for the infant. He believed that the induction of labor compared in gravity, when the interests of both mother and child were considered, with other major obstetric operations. The author then cited six cases to illustrate the statements he had made. He strongly urged the importance of conducting cases of induced labor in such a manner that the patient should be in favorable condition for a major operation, if necessary. He did not believe it justifiable during induced labor to make efforts at delivery by forceps or version unless the conditions were such as to make it reasonably certain that these operations would be immediately successful. If engagement of the head did not develop during induced labor the use of the forceps

was a dangerous procedure. If the operator was sure of the size and contour of the pelvis, and reasonably certain of the comparative size of the fetus, version, where the head did not engage, was the safer operation. The writer would not resort to delivery by section in a case where efforts at delivery by forceps or by version had been made. He believed that with careful antiseptic technique it was possible to introduce bougies within the uterus, or even to employ dilating bags without infecting the patient. These procedures should not cause lacerations and should not essentially wound the epithelia of the genital tract. It was impossible, however, to make tentative traction with forceps, or to practice the manipulations necessary in attempting version without producing lesions in the genital tract through which infection might enter. It was his practice, then, to decline celiohysterotomy in all cases where forceps or version had been tried. In severely septic cases, the child being dead and unsuccessful efforts having been made at delivery, he believed that the Porro operation would give the best results. In cases where forceps or version had been tried without success, if the child was living, he believed that the consultant should again try which ever of these procedures he thought best, utilizing Walcher's position if advisable; failing in these craniotomy should be done. As to pubiotomy, a sufficient number of cases had ben published to show that the operation, like all other surgical procedures, was not without its dangers and disadvantages. A maternal mortality of from 5 to 7 per cent. and a fetal mortality of 17 per cent. indicated its severity. As to delivery by abdominal section, all things considered, and especially when the fetal mortality was taken into consideration, the claims of abdominal section for safe delivery of mother and child could not be disregarded. He did not believe that at the present time a dogmatic opinion could be formed concerning any one method of delivery. Another factor of importance was the value placed by parents upon the life of the child.

Dr. Egbert H. Grandin of New York said the conclusions and line of argument advanced by Dr. Reynolds were in accord with those which he presented in a thesis read before the society seventeen years ago entitled, "A Plea for the Elective Cesarean Section." He contended then that this operation was ideal, and although seventeen years had elapsed since, he had not seen fit to change his position. As to pubiotomy, he would advise it in preference to symphyseotomy, although he had not done the former operation, but had performed symphyseotomy twice, with living mothers and living children, and, so far as he knew, with no disability on the part of the women.

Dr. Lapthorn Smith of Montreal condemned pubiotomy. Last summer he performed two cesarean sections, and could testify to the surprising ease with which the operation was done in both cases.

Dr. James Clifton Edgar of New York was uncertain as to where to draw the line between Class A and Class B in the cases discussed by Dr. Reynolds; that is, the antepartum cases, and the early intrapartum cases. It occurred to him that if Class B, or the early intrapartum class, was moved a little forward, and the women not allowed to stay in labor quite so long, instead of a mortality of three per cent., as reported by Dr. Reynolds, it would approach one per cent. in the antepartum cases. Where cesarean section was undertaken in the latter part of pregnancy there was difficulty in securing good drainage. Pubiotomy did not appeal to him, although he had never done it. He had, however, done six symphyseotomies.

Dr. Robert A. Murray of New York thought that eventually, in the vast majority of cases, obstetricians would gradually come to the point where they would let women go to labor prepared to do a cesarean section, and not interfere with high forceps, or version, or any other method that would produce traumatism of the cervix and possibly cause infection which would defeat the result to be gained from a clean cesarean section.

Dr. Robert L. Dickinson of Brooklyn, N. Y., said the only cesarean section case he lost was a young woman who suffered from toxemia throughout her pregnancy. She was operated on at the beginning of labor pains, but gradually died from a lack of resistance after an easy cesarean section. For many years obstetricians had had control of the second stage of labor, and with cesarean section, forceps, and version the obstetrician could do what he chose. But the obstetrician had stood helpless before the difficult dilatations and before badly developed cervical conditions. He thought it was unobstetrical to insert a bougie into the uterus, as it might loosen the placenta and carry infection. We could not be sure of absolute cleanliness.

The papers were further discussed by Drs. E. W. Cushing of Boston, George Gellhorn of St. Louis, Mo.; Seth C. Gordon of Portland, Me.; Malcolm McLean of New York; Willis E. Ford of Utica, N. Y.; Philander A. Harris of Paterson, N. J., and the discussion was closed by the essayists.

(To be continued.)

AMERICAN SURGICAL ASSOCIATION.

Twenty-eighth Annual Meeting, Held in Washington, D. C., May 7, 8, and 9, 1907, in Conjunction with the Congress of American Physicians and Surgeons.

(Special Report to the Medical Record.)

Tuesday, May 7—First Day.

The Address of the President.—Dr. Dudley P. Allen of Cleveland took as the subject of his address, "the training of the surgeon." He said that during the past generation the progress of surgery had been tremendous, due mostly to the introduction of anesthesia and of asepsis. It did not seem possible for another generation to make as great strides. The main problem at present that needed solution was in the line of the nonoperative treatment of cancer. A very practical problem that was always with us was, not only how to impart to students our knowledge of what has been done, but how to advance our knowledge in the future. In country districts there would always be a demand for men with a general training but in the populous centers there would always be need of the specialists, and it was of them that this paper specially treated. The specialists should have a thorough training in all medicine, so that the surgeon might be a competent judge as to the advisability of operation, and should be able to make a diagnosis for himself as to the region of the operation, as, for instance, in distinguishing the location of pus collections in the lower pleural, upper abdominal, or liver regions. The surgeon should be able to make a diagnosis of early pregnancy in order to avoid operation on the gravid uterus; he should be able to appreciate ear conditions and their relation to brain work, etc. All of these were needed even though he limited his work to general surgery. Above all he should be able to say when operation was the best treatment. Some surgeons took advantage of every possible surgical condition, and operated with the consent of the patient as the only other necessary requirement. The public had not yet learned that the benefit of the hospital depended on its administration and on the surgeon. As to the methods of instruction of the medical student opinions varied greatly. Some believed that didactic work was essential, others that it was useless, some would teach in large clinics, others only in sections; some said that operative work on the cadaver was essential, others that it only begot carelessness. Some said that the only operative work worth doing was on mammals. Some said that the elective course in the medical school was desirable, others that it was bad. The schools all differed as to the method of instruction, but all agreed that four years were not enough for specialist training, that

a specialist developed in four years of medical study must be very narrow. The end might be attained in various ways but all needed training in two branches—surgical pathology and surgical diagnosis. They needed to be taught to write accurate histories, to do which they must make accurate examinations. Section work was necessary to enforce accurate knowledge. The student by recitation, discussion, and written report, must show what he had learned. The student should be taught to be not merely a consumer but also a producer of knowledge. To advance knowledge he must understand the pathology of his diseases both gross and microscopical, and on that base his diagnosis. Laboratory teaching was most important for the teaching of pathology, but the laboratory diagnosis must not be considered sufficient to set aside the clinical diagnosis. Again it must always be borne in mind that the laboratory diagnosis was no more certain than the man behind the microscope. The student must learn to apply his laboratory work to his clinical material. It was desirable to remember the teachings of the earlier days, for our modern anesthesia and asepsis had tended to lead to laceration of the tissues and delay in operation. It was necessary to keep up the clean-cut and the rapid work. The tendency to omit all didactic work from the fourth college year was a bad one, not only for the student, but also for the teacher; because the teacher became wearied of repetition of the same work to section after section and finally the better men gave it up, and it fell to the lot of the younger and less experienced members of the teaching staff. Dogmatic teaching was always popular but the broad clinician as a teacher was also always needed. It was time enough to begin the study of a specialty after the end of the fourth year. In Canada five years would soon be required, and in Europe six years was demanded for the general training of the medical man. There was no training better than a hospital service, and that long enough for the student to become competent to do operative work. It would be a great advance if the latter years of a man's study could be spent in the hospital and in the study of the pathological work. To answer in a single word "How shall we train our surgeons," we must answer "thoroughly." And the test might well be made by a board of national examiners which would soon create an international recognition of that standard. The instruction should be thorough and broad, there should be a long hospital service, and postgraduate study. There should be a national standard of proficiency.
